Molluscum contagiosum represents a common viral infection of the skin (and sometimes mucous membranes) of children and adolescents. It is caused by a poxvirus and has not been grown in culture. The virus replicates within the cytoplasm[15] and is represented by four viral types based on DNA analysis: MCV-1 to MCV-4.[42] MCV-1 accounts for more than 90 percent of infections in the United States.[15,42] The subtypes do not show site specificity. MCV-2 was reported to be seen most commonly in patients infected with human immunodeficiency virus (HIV).[17,42]

Epidemiology

The disease is seen with increasing frequency in sexually active and immunodeficient individuals. Infection occurs at any age, with the highest frequency seen in patients younger than 5 to 10 years old.[9,15] The disease is two to three times more common in school-aged and sexually active males than in females. Transmission is via close contact. Spread is reported to occur via fomites. The incidence of disease is highest in warm climates and in areas of overcrowding.

Clinical Manifestations

The incubation period for molluscum contagiosum is 2 to 7 weeks, but it has been reported to occur at 1 week of age. Typical lesions are 1 to 5 mm, dome-shaped, skin-colored or pink papules with a distinctive central umbilication (Fig. 60B-1). Giant lesions 1 to 2 cm can be seen. According to an epidemiologic survey conducted at three pediatric dermatology centers, fewer than 15 lesions usually are seen.[15] In children, molluscum contagiosum is seen most frequently on the face, neck, trunk, and extremities but may be seen on any part of the body, including the mucous membranes.[9,15,41] Periocular lesions may lead to secondary keratoconjunctivitis or trachoma. In some cases, molluscum contagiosum is a sexually transmitted infection, raising the issue of sexual abuse when infection is seen in the genital area. The most common etiology of genital molluscum contagiosum is autoinoculation; however, if the lesions occur solely in the genital area, or a question exists about the patient's social situation, the possibility of abuse should be explored.

Atypical lesions of molluscum contagiosum are seen more commonly, particularly with the improved survival rates of patients with acquired immunodeficiency syndrome (AIDS) and other immunocompromised states.

FIGURE 60B-1 ■ Grouped dome-shaped papules of molluscum contagiosum on the skin of the abdomen. (See companion Expert Consult website for color version.)

FIGURE 60B-2 ■ Diffusely distributed, isolated, monomorphous skin-colored papules on the thigh of a child typical of Gianotti-Crosti syndrome.

The incidence of molluscum contagiosum in HIV infection is 5 to 18 percent. With improved antiretroviral therapies, molluscum contagiosum has decreased in this population.[11,15]

Molluscum contagiosum lesions in immunocompromised patients often are large, are situated more deeply in the epidermis, and may number in the hundreds. HIV-positive adults usually have molluscum contagiosum on the face, neck, and trunk. In a study of immunocompromised children, molluscum contagiosum was not considered to be common or severe, however. This study included only six patients, and two were disease-free and thought to be immunocompetent at the time of onset of the infection. This and other studies suggest that the presence and degree of cellular immunodeficiency are important in the presentation of molluscum contagiosum.

Patients with atopic dermatitis may be predisposed to develop more severe molluscum contagiosum infection. Available information is insufficient to know if this development is related to the dermatitis itself with its well-described barrier dysfunction or to the use of corticosteroids or other topical agents. The term *molluscum dermatitis* is used to describe an eczematous eruption, more commonly seen in patients with atopic dermatitis, which may occur around molluscum contagiosum lesions and is thought to represent a delayed-type hypersensitivity reaction to viral antigens in the dermis.

Molluscum contagiosum infections in healthy individuals usually resolve spontaneously over the course of several months to 3 to 5 years. For this reason, limited infections can be observed expectantly. More diffuse infections or infections that show continued extension can be considered for treatment. No definitive treatments are available for molluscum contagiosum. Most treatments, similar to those used for warts, are destructive. Immune enhancement for these infections has been tried, but its utility has not been proved. Multiple treatments have been used, although utility is uncertain in all but curettage.

PARVOVIRUS B19 INFECTIONS

See Chapter 151.

GIANOTTI-CROSTI SYNDROME (PAPULAR ACRODERMATITIS OF CHILDHOOD)

Gianotti-Crosti syndrome (papular acrodermatitis of childhood) is a viral exanthem first reported in 1955 by Gianotti,[26] who described a group of children who presented with predominately acrally located, skin-colored or slightly erythematous, lichenoid papules (Fig. 60B-2).[68] The flexures usually were spared. Involvement of the buttocks or trunk was seen in some cases. No involvement of mucous membranes occurred. Patients generally were healthy. The initial reports showed prior infection with hepatitis B. The eruption lasted 2 weeks to 2 months.

Since the initial report, similar cases have been associated with other infections, such as Epstein-Barr virus, coxsackievirus, echovirus, other viruses, and streptococcal disease.[47] Most cases are thought to be viral in origin and often caused by Epstein-Barr virus. Topical therapies do not hasten resolution of the exanthem.

ASYMMETRIC PERIFLEXURAL VIRAL EXANTHEM

Some children have been described with discrete or grouped lichenoid papules or urticarial papules beginning around flexures or the torso (Fig. 60B-3).[25] The eruption generalizes over several days and can appear as a more diffuse case of the papular acrodermatitis of childhood. The condition also has been described as the unilateral laterothoracic viral exanthem and seems to be associated with the same infectious agents as described in papular acrodermatitis of childhood.[7] The evolution of this condition is similar to that in the papular acrodermatitis of childhood.

FUNGAL INFECTIONS

Superficial fungal infections, which include dermatophytes, yeast, or dematiaceous fungi, are encountered frequently in general pediatric practice. Particularly in an immunocompromised patient, fungal infections also may involve deeper cutaneous structures and other organ systems. This section focuses on the skin manifestations, diagnosis, and treatment of pediatric fungal infections.

SUPERFICIAL FUNGAL INFECTIONS

Dermatophyte Infections

Dermatophytes invade and grow in hair, nails, and the outer layer of the skin known as the *stratum corneum*. These lesions vary in appearance based on the site of infection and are named accordingly.

Tinea Capitis

Also known as *scalp ringworm*, tinea capitis is seen frequently in prepubertal children. The causative organisms vary according to country; in North America, tinea capitis is caused largely by *Trichophyton tonsurans* and less often by *Microsporum canis*.[16,56,70] *M. canis*, a zoophilic dermatophyte common to suburban and rural areas, can be transmitted to children who handle infected animals such as cats, dogs, and certain rodents; however, it does not spread between humans.[56] Thick, white patches of broken hair that fluoresce under Wood lamp examination characterize these lesions.

Human-to-human transmission of *T. tonsurans* occurs through the shedding of spores from infected skin scales and hair on items such as clothing, bed linen, combs, and hairbrushes. Lesions caused by *T. tonsurans* do not fluoresce under a Wood lamp and vary in appearance from diffuse scaling of the scalp to circumscribed areas of scaling and erythema with or without hair loss, and, in dark-haired individuals, to scaly patches of hair loss that may leave small dark hairs in the follicles (black-dot ringworm) (Fig. 60B-4). Tinea capitis lesions may be associated with suboccipital or posterior cervical lymphadenopathy and may produce more inflammatory lesions, including scaly, pustular areas of hair loss and formation of a kerion—a boggy, erythematous mass with follicular pustules that may lead to permanent hair loss and scarring if left untreated (Fig. 60B-5).[16,35,70] Another hypersensitivity response to the dermatophyte infection is a dermatophytid or id reaction, which involves papulovesicular

FIGURE 60B-4 ■ Nonscarring alopecia associated with tinea capitis. (See companion Expert Consult website for color version.)

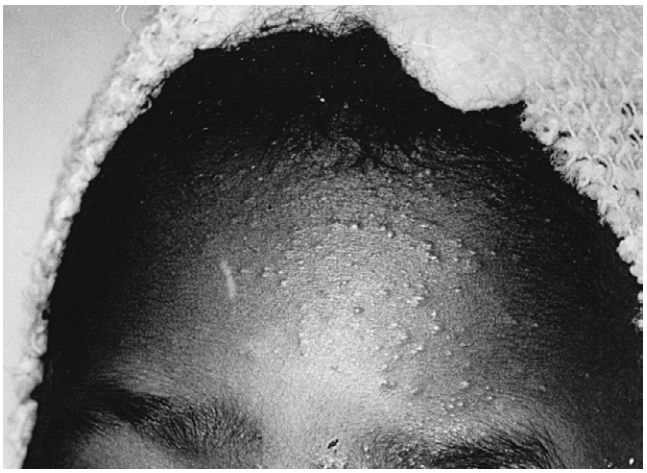

FIGURE 60B-6 ■ Multiple skin-colored papules and pustules on the forehead typical of an id reaction to tinea capitis.

FIGURE 60B-5 ■ Indurated tumor on the scalp typical of kerion. (See companion Expert Consult website for color version.)

FIGURE 60B-7 ■ Diffuse scaling plaques on the face caused by tinea faciei. (See companion Expert Consult website for color version.)

inflammatory eruptions adjacent to or distant from the site of the primary infection (Fig. 60B-6).[6]

Tinea capitis must be distinguished from alopecia areata, which consists of patches of total hair loss without scalp changes, and trichotillomania, which may be associated with excoriations, varying lengths of broken hairs, and ill-defined patterns of hair loss. Differential diagnosis also includes traction alopecia, seborrheic dermatitis, psoriasis, and pityriasis amiantacea. In addition, inflammatory lesions of tinea capitis may be confused with bacterial pyodermas of the scalp.[35,56,70]

Tinea Corporis

Tinea corporis is dermatophyte infection of the trunk or extremities. Lesions appear as erythematous patches or plaques with well-demarcated, annular borders that may be scaly, pustular, or vesicular.[35,56,70] The application of potent topical corticosteroids may obscure these characteristic borders, resulting in a manifestation termed *tinea incognito*.[56] The differential diagnosis includes seborrheic, atopic, and contact dermatitides; psoriasis; and granuloma annulare.[35,70]

Tinea Faciei

Dermatophyte infections of the face in children are characterized by erythematous, scaly plaques that may be unilateral or occur in a "butterfly" distribution, mimicking cutaneous findings of systemic lupus erythematosus and other collagen vascular diseases (Fig. 60B-7). As with

FIGURE 60B-8 ■ Annular scaling plaque on the upper inner thigh caused by tinea cruris. (See companion Expert Consult website for color version.)

tinea corporis, differential diagnosis includes seborrheic, atopic, and contact dermatitides.[35,70]

Tinea Pedis

Tinea pedis, which occurs more commonly in adolescents than in prepubertal children, is dermatophyte infection involving the feet. Findings vary and may be vesicles or erosions over the instep of the feet, fissuring between the toes with surrounding erythema and scaling, or diffuse scaling of the soles in a "moccasin-like" distribution. Differential diagnosis includes juvenile plantar dermatosis, dyshidrotic eczema, atopic dermatitis, contact dermatitis, granuloma annulare, scabies, psoriasis, and erythrasma.[35,56,70]

Tinea Cruris

Also predominately seen in adolescents, particularly boys, tinea cruris often occurs in association with tinea pedis and is transmitted through indirect or direct contact with infected skin scales or hair. Risk factors include obesity, friction, moisture, and tight clothing. The characteristic lesions are usually symmetric, well-demarcated, erythematous, scaly eruptions in the inguinal and inner thigh area with potential spread to the buttocks and perianal region. These lesions also may have a raised papular or pustular edge and often are very pruritic, leading to lichenification in chronic disease (Fig. 60B-8). The differential diagnosis includes seborrheic dermatitis, *Candida* intertrigo, flexural psoriasis, irritant dermatitis, contact dermatitis, and erythrasma.[35,56,70]

Tinea Unguium

The term *onychomycosis* refers to fungal invasion of the nail plate, which is termed *tinea unguium* when the infection is caused by dermatophytes. The lower incidence of tinea unguium in children compared with adults may be due to faster nail growth, decreased likelihood of nail trauma, and less exposure to tinea pedis, which often is seen concurrently with onychomycosis.[37,60] Clinical findings of infection include superficial white patches on the surface of the nail plate, white spots under the nail, and yellowing and thickening of the nail plate that usually extends from the distal to the proximal end (Figs. 60B-9 and 60B-10). The differential diagnosis includes psoriasis, lichen planus, hereditary onychodystrophy, and acquired trachyonychia, all of which may be distinguished from tinea unguium by their diffuse nail involvement as opposed to the more limited disease of a dermatophyte infection. Tinea unguium also may mimic *Candida* infection of the nails, but the latter disease differs in that it tends to spread distally from the proximal nail plate.*

FIGURE 60B-10 ■ White superficial plaques typical of superficial white onychomycosis. (See companion Expert Consult website for color version.)

*References 16, 30, 35, 37, 60, 70.

Diagnosis

Light microscopy examination with potassium hydroxide should show spores in infected scalp hairs of tinea capitis and branching hyphae in affected nail samples or skin scrapings from advancing margins of lesions on the body (Fig. 60B-10). Fungal culture on Sabouraud dextrose agar treated with chloramphenicol and cycloheximide provides a growth medium selective for dermatophytes and may aid in differentiating various species. Rarely, biopsy may be required for definitive diagnosis.[16,35,56,70]

Treatment

Localized lesions of tinea corporis, faciei, pedis, and cruris generally respond to a 2- to 4-week course of topical antifungals, such as clotrimazole, tolnaftate, ciclopirox olamine, amorolfine, or terbinafine.[16] Severe or refractory disease may require oral antifungal medications. Recurrence of tinea pedis can be prevented by avoiding occlusive footwear and keeping the feet clean and dry.[56]

Griseofulvin is the only oral antifungal medication approved by the U.S. Food and Drug Administration (FDA) for use in children. Many agents, including terbinafine, itraconazole, and fluconazole, have been used successfully as off-label alternatives, however, despite limited data regarding their safety and efficacy in children.

Griseofulvin remains the gold standard for the treatment of tinea capitis in the United States. The approved dose of microsized griseofulvin is 11 mg/kg/day for 6 to 8 weeks; however, 20 to 25 mg/kg/day often is required to achieve an adequate response.[64] A 2- to 4-week course of terbinafine also has been shown to be as effective as griseofulvin, particularly in the treatment of tinea capitis caused by *Trichophyton* spp.[21,23,33,65] For *Microsporum* infections, higher doses or longer duration of therapy with terbinafine may be required.[21,23,33,43,65] Studies have shown that a regimen of fluconazole 6 mg/kg/day for 3 to 6 weeks has a cure rate comparable to that of griseofulvin.[22,33,65] Continuous or pulse itraconazole therapy of 5 mg/kg/day has been noted to result in significant improvement and even cure in *Trichophyton* and *Microsporum* tinea capitis by 6 weeks; however, infection with *Microsporum* may require a longer duration of treatment with itraconazole compared with effective courses for *Trichophyton* infection.[27,33,31] In addition, concomitant topical therapy with selenium sulfide 1 to 2.5 percent shampoo in affected individuals and household contacts reduces the number of viable spores and prevents the spread of infection.[28,56,59]

At present, no antifungal agent is approved by the FDA for treatment of onychomycosis in children, and data are limited regarding efficacy of topical and oral antifungal agents. Topical agents have poor penetration into the nail plate, usually leading to an inadequate response rate. Treating concurrent tinea pedis infections with topical therapy may help prevent recurrences of tinea unguium, however. Although griseofulvin is the drug of choice for treating other dermatophyte infections, it is not recommended for the treatment of onychomycosis because of the lengthy course (≤18 months), inadequate response, and high recurrence rate.

Terbinafine 3 to 6 mg/kg/day for 6 to 12 weeks, continuous or pulse itraconazole 5 mg/kg/day for 3 months, and fluconazole 3 to 6 mg/kg once a week for 12 to 26 weeks have been reported as safe, effective, and well-tolerated alternatives.[30,36,50,65] Because of their keratinophilic and lipophilic natures, these agents accumulate in the stratum corneum and persist at high concentrations in the nails for months, allowing for shorter courses of therapy.[30,31,36,37,65] Terbinafine may be crushed and taken with or without food. Optimal bioavailability with itraconazole capsules occurs when taken with fatty foods, whereas itraconazole solution should be taken on an empty stomach and may be associated with a higher incidence of gastrointestinal side effects than capsules. Studies regarding use of fluconazole for treatment of onychomycosis in children are limited, but successful therapy has been reported at a pulsed dose of 3 to 6 mg/kg once a week for 3 months.[30,36,65]

Candida

The most common cause of fungal infection in healthy and immunocompromised children is *Candida*, and *C. albicans* accounts for most cases. These yeast forms have a predilection for moist, warm areas of the body such as mucosal surfaces and intertriginous regions and often colonize these areas, becoming part of the normal flora. Disease is caused by overgrowth and infiltration into the epidermis. Superficial infections may be seen in healthy individuals and individuals with predisposing risk factors, such as prematurity; low-weight; diabetes mellitus; antibiotic, corticosteroid, or oral contraceptive therapy; and other immunocompromised states. These individuals also are more likely to develop systemic candidiasis.[16,24,70]

Thrush is characterized by superficial, sometimes tender, white plaques on oral mucosa that reveal denuded, erythematous bases when scraped off (Fig. 60B-11). These manifestations must be distinguished from other oral cavity lesions, such as aphthous stomatitis, epidermolysis bullosa, herpes simplex, hairy leukoplakia, lichen planus, geographic tongue, erythema multiforme, and burns.[70] Use of pacifiers in infants may increase the risk for development of thrush and colonization of the organism.[5] Oropharyngeal candidiasis may spread to the

esophagus in immunocompromised individuals and lead to difficulty with feeding.

Diaper candidiasis appears as beefy, erythematous plaques that involve the inguinal creases and perianal region and often are associated with satellite (or surrounding) erythematous papules, plaques, or pustules (Figs. 60B-12 and 60B-13). These lesions may cause discomfort when the infant urinates onto affected skin. Superinfection with *Candida* should be suspected when irritant diaper dermatitis fails to improve within several days. Other lesions that may be confused with diaper candidiasis include psoriasis, Langerhans cell histiocytosis, and seborrheic dermatitis.[70]

Thumb-sucking or other trauma near nail beds may lead to nontender, erythematous swelling at the base of the nails termed *paronychia* (Fig. 60B-14). Some cases are complicated by *Candida* infection. Differential diagnosis of these lesions includes psoriasis, bacterial infection, lichen planus, and pachyonychia congenita. *Candida* also may produce onychomycosis, but its distribution usually involves the proximal nail plate, in contrast to dermatophytosis of the nails, which more commonly affects the distal nail plate.[70]

Adolescent girls may present with vulvovaginal candidiasis, which is characterized by thick, white discharge and white plaques on irritated, erythematous vaginal mucosa. These lesions may cause vaginal itching and dysuria.[70]

Diagnosis of localized *Candida* infection usually is made clinically. Microscopic examination of potassium hydroxide–prepared scrapings of skin and mucosal lesions reveals pseudohyphae and elongated budding yeast forms. Positive cultures of infected material on Sabouraud dextrose agar or cornmeal agar may signify infection or benign colonization. Biopsy rarely is required for establishing a definitive diagnosis.

Treatment of localized *Candida* infection depends on good hygiene practices and maintenance of a dry environment in the susceptible area. Localized infections usually respond well to topical antifungal therapy. Nystatin solution is the first-line agent used for thrush, but oral fluconazole or itraconazole and intravenous amphotericin B may be required to treat recurrent, refractory, or extensive disease, especially in immunocompromised children.[19] Nystatin or imidazole creams in conjunction with frequent diaper changes, barrier creams, and sometimes low-strength topical steroids are the recommended treatment for diaper candidiasis. Paronychia also is susceptible to nystatin and imidazole creams but may require oral therapy. Vulvovaginal candidiasis often can be treated successfully with topical azole medications, but oral azoles are recommended for refractory or recurrent cases. Adolescents can be treated with a single, 150-mg dose of oral fluconazole.[19,54]

Congenital candidiasis, a rare form of infection acquired in utero as a result of *Candida* chorioamnionitis, can manifest in full-term and premature neonates within the first few days of life as a diffuse, erythematous, papular eruption that progresses to formation of vesicles and

pustules, and subsequently crusting and desquamation. Palms and soles also may be affected. Term infants with congenital candidiasis rarely develop systemic manifestations, and the infection usually resolves spontaneously or with topical antifungal agents, such as nystatin, imidazoles, or allylamines. Premature neonates with very low birth-weight are at risk for developing ecchymosis and necrosis of the skin with dissemination of the *Candida* infection, requiring treatment with systemic antifungal medication. Congenital candidiasis in these premature infants may manifest as sepsis or pneumonia without cutaneous findings as well.[1,16,67]

Differential diagnosis of congenital candidiasis includes epidermolysis bullosa and infection with *Listeria monocytogenes*, *Staphylococcus*, herpesvirus, and syphilis.[14] Early diagnosis is established by histologic examination of the placenta and umbilical cord, which shows the characteristic pseudohyphae and spores and white microabscesses.[1,14] Microscopic examination and culture of the skin lesions can confirm the diagnosis.

FIGURE 60B-15 ■ Pustules and papules on the face and scalp owing to neonatal cephalic pustulosis. (See companion Expert Consult website for color version.)

Malassezia

Malassezia spp., most notably *Malassezia furfur*, are lipophilic yeast forms that are found more readily in humid, tropical environments and are part of the normal skin flora in humans. Colonization begins in the neonatal period and increases with age.[4] *Malassezia* is the organism thought to be responsible for neonatal cephalic pustulosis and tinea (or pityriasis) versicolor in older children, adolescents, and young adults. Invasion of the organism through indwelling catheters, particularly catheters being used for intralipid infusion in premature infants with very low birth-weight also may lead to sepsis and death.[3,58,67] *Malassezia* also has been implicated in the pathogenesis of seborrheic dermatitis, atopic dermatitis, and psoriasis, although this implication is controversial.*

Neonatal cephalic pustulosis is a self-limited disease characterized by scattered, erythematous papules and pustules in a head-and-neck distribution (Fig. 60B-15). Follicular accentuation and comedones are not observed. Diagnosis usually is made clinically, but may be confirmed by microscopic findings.[4,16,67]

Tinea versicolor is characterized by macules with fine scales that are distributed on the upper body and neck. The macules may appear hypopigmented in dark-skinned individuals or tan or dark brown in lighter skinned individuals (Fig. 60B-16). Differential diagnosis includes vitiligo, pityriasis alba, pityriasis rosea, postinflammatory hypopigmentation, melasma, seborrheic dermatitis, contact dermatitis, and tinea corporis. Lesions of tinea versicolor are fluorescent yellow to orange under Wood lamp. Microscopic examination of potassium hydroxide–prepared scrapings of the lesions shows a "spaghetti and meatball" appearance owing to the presence of short, curved hyphae and round spores. Biopsy of the lesions, which usually is unnecessary, reveals the characteristic hyphae and spores invading the stratum corneum.

The recommended treatment is application of 2.5 percent selenium sulfide or ketoconazole shampoo. Other topical agents, such as ciclopirox, terbinafine solutions, sodium hypochlorite, and other azoles, also may be effective. Short 1- to 5-day courses of oral itraconazole, fluconazole, and ketoconazole in single daily doses have been suggested as effective treatments; however, these agents are not approved by the FDA for treating tinea versicolor in children because of their limited safety and efficacy profiles.[6,18,55] It is important to advise patients that skin discolorations may take months to resolve and that recurrences are very common and may require retreatment.[16,35,55,67,70] *Malassezia* sepsis responds well to removal of indwelling catheters and rarely requires systemic antifungal therapy.[67]

FIGURE 60B-16 ■ Well-circumscribed annular scaling plaques on the neck typical of tinea versicolor. (See companion Expert Consult website for color version.)

Chromoblastomycosis

Fonsecaea pedrosoi, and less commonly *Cladophialophora carrionii*, and *Phialophora verrucosa*, are found in tropical

*References 3, 32, 35, 46, 49, 62, 69.

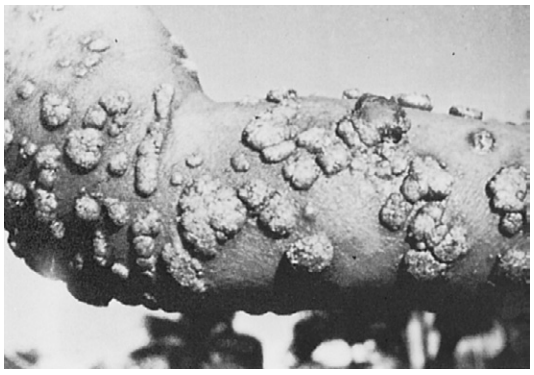

FIGURE 60B-17 ■ Chromoblastomycosis. The wart-like growth of epidermis and dermis is a result of traumatic implantation of the etiologic agent and subsequent autoinoculation from scratching. The agent was *Fonsecaea pedrosoi*.

FIGURE 60B-18 ■ Brown patch on the palm of the hand caused by tinea nigra palmaris. (See companion Expert Consult website for color version.)

climates and are organisms responsible for causing chromoblastomycosis, a chronic granulomatous disease affecting skin and subcutaneous tissue. Infection is acquired through traumatic inoculation into the skin. Cutaneous manifestations are described as pink papules that progressively enlarge to become tender, pruritic, hyperkeratotic nodules or verrucous plaques (Fig. 60B-17). Scratching may lead to secondary infection or result in autoinoculation of the organism to other areas of the body. Infection may lead to scarring of lymphatic vessels causing obstruction and lymphedema.[8,20,52,57]

Differential diagnosis includes tuberculosis, sporotrichosis, blastomycosis, leishmaniasis, and squamous cell carcinomas. Potassium hydroxide smears of skin scrapings reveal characteristic dark brown, round, sclerotic bodies with horizontal or vertical septa and thick, pigmented hyphae. Sclerotic bodies also are identified easily on hematoxylin and eosin stain. In addition, biopsy of the chromoblastomycosis lesions shows granulomatous inflammation with macrophages and neutrophils and a hyperkeratotic, hyperplastic epidermis with microabscesses.[8,20,57]

Treatment of localized lesions involves surgical excision, cryotherapy, or heat therapy. Chemotherapy with 5-fluorocytosine and antifungal agents such as azoles, amphotericin B, and terbinafine has been used with some success in more widespread disease.[8,20,66]

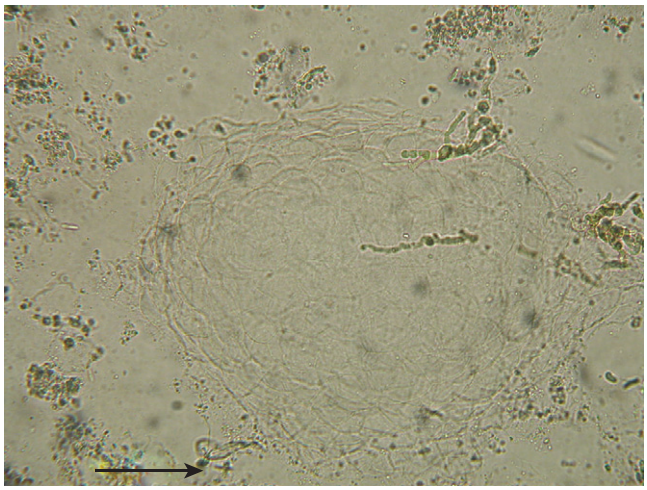

FIGURE 60B-19 ■ Septate hyphae seen by potassium hydroxide examination of scale from the patient in Figure 60B-18. (See companion Expert Consult website for color version.)

Tinea Nigra

Tinea nigra, caused by the organism *Hortaea werneckii*, is a superficial fungal infection seen primarily in children and adolescents.[35,44,51] The organism is found in soil, wood, sewage, salted dried fish, and vegetation, mainly in beach environments of Central and South America, Africa, Asia, and, less frequently, in the United States and Europe. Transmission occurs by direct contact.[44,51,53]

Tinea nigra usually is characterized by an asymptomatic, well-demarcated, single brown to black macule or patch primarily on the palm, but may involve other areas of the body as well (Fig. 60B-18). Lesions grow slowly and usually are nonscaly.[35,51] Tinea nigra lesions may mimic melanoma, lentigines, junctional nevi, and the hyperpigmented patches of Addison disease.[35,51,53] Under microscopic examination, potassium hydroxide–prepared scrapings of the lesion show yellow to light brown, branched, septate hyphae (Fig. 60B-19).[35,53] Diagnosis is confirmed further by culture, which grows oval to spindle-shaped, moist, shiny, black colonies on Sabouraud agar.[51]

Tinea nigra has been treated successfully with keratolytic ointments or solutions, which include salicylic acid and benzoic acid and azole and allylamine creams.[35,51,53] Scraping the lesion with a scalpel also can remove the discoloration.[53]

Trichosporonosis

Trichosporon spp., which are found in soil, vegetation, animal feces, and stagnant or fresh water, have a worldwide

distribution with a predilection for tropical climates. They also may colonize human skin and digestive, respiratory, and urinary tracts. In immunocompetent individuals, *Trichosporon* organisms produce superficial fungal infections of the hair shaft termed *white piedra* and, less commonly, are one of the causes of onychomycosis. Systemic disease, termed *trichosporonosis*, may develop in immunocompromised patients, particularly neutropenic patients with hematologic malignancies, and in premature infants with very low birth-weight with colonization of indwelling catheters.[16,38]

White piedra is described as soft white, tan, or reddish-green nodules encircling the hair shaft that may be associated with scalp hyperkeratosis, brittle hair, and alopecia. These concretions do not fluoresce under Wood lamp examination. Differential diagnosis includes tinea capitis, pediculosis, black piedra, monilethrix, trichomycosis axillaris or pubis, and trichorrhexis nodosa.[38,71] Skin manifestations of disseminated infection include desquamation and serous drainage, purpuric papules or nodules with central ulceration or necrosis, and white plaques.[16,61]

Fungal blood culture reveals germ tube–negative and urease-positive yeast. Potassium hydroxide mounts of affected hair show hyaline septate hyphae, pseudohyphae, rectangular arthroconidia, and spherical blastoconidia that circumscribe the hair shaft.[20,40,61] Culture on Sabouraud dextrose agar shows cream-colored colonies that become wrinkled in a few weeks.[39] Biopsy specimen of skin lesions shows perivascular inflammation with budding yeast cells.[34]

White piedra is a difficult disease to treat because of the high recurrence rate. Although the American Academy of Dermatology Guidelines Committee recommends shaving affected hair to eradicate white piedra,[15] cosmetic and social considerations render this approach an unfavorable option for most patients. Topical antifungal agents that have been tried with varying degrees of success include ciclopirox olamine, imidazoles, chlorhexidine solution, 2.5 percent sulfide shampoo, zinc pyrithione, Castellani paint, mercury bichloride solution, 5 percent sulfur ointment, 5 percent ammoniated mercury ointment, and amphotericin B lotion. Although topical treatments may clear hair shaft concretions, they are not as effective at preventing recurrence. Because of their ability to bind keratin and their excretion in sebum, oral antifungal agents such as itraconazole may achieve higher concentrations in hair follicles and lead to greater success in eliminating colonized *Trichosporon* organisms and preventing relapse.[39,40]

Disseminated trichosporonosis is associated with high morbidity and mortality rates. It has been treated with varying degrees of success using amphotericin B with or without 5-fluorocytosine and the newer azole drugs, such as voriconazole.[2,38]

SECTION **XI**

OCULAR INFECTIOUS DISEASES

CHAPTER 61

Ocular Infections

Mohamed Hussein • Aaron M. Miller • Paul G. Steinkuller

The eye can be affected by infections and infestations manifested as primary diseases or as part of systemic processes. Some infections are vision-threatening, whereas others may have important implications for a generalized disease process. Ocular findings can help narrow the differential diagnosis list in some systemic diseases, such as congenital viral infections. A helpful approach in this regard is to use an anatomic scheme that reflects the primary site of ocular involvement. This chapter proceeds systematically from anterior to posterior, from infections involving the eyelids and superficial ocular surface to those involving deeper tissue and intraocular structures, and concludes with a discussion of infections involving the orbit. Some disease sites overlap, and duplications are therefore unavoidable.

Most infectious processes involving the eye can be diagnosed accurately by following the standard medical protocol: history, examination, laboratory analysis, differential diagnosis. The three simple basic tools—a visual acuity chart, a pen light, and a direct ophthalmoscope—facilitate establishing a diagnosis in most instances. In some cases, however, special ophthalmologic testing such as a slit-lamp examination, indirect ophthalmoscopy, ocular ultrasound, Gram stain and culture, or a biopsy are required. One of the cardinal rules in ophthalmology is *always* to measure the vision as the very first examination step.

INFECTIONS OF THE EYELIDS

The eyelids are composed of connective tissue, hair follicles, sweat and sebaceous glands, smooth and striated muscles, sensory and motor nerves, and vascular elements. The skin covering the eyelids is the thinnest of the entire body. The inner surface of the eyelid is covered by the palpebral conjunctiva. Bulbar conjunctiva covers the surface of the globe. Connecting these two conjunctival parts is the conjunctival fornix, which designates the most posterior limit of the conjunctiva. Sebaceous glands, the glands of Zeis, are associated with eyelid hair follicles. Meibomian glands, located within the tarsal plates of the eyelids, are also sebaceous and drain at the posterior aspect of the lid margin.[111]

Infection of the eyelids may be generalized or focal. Involvement of the skin by an infectious agent is referred to as *dermatoblepharitis*. *Staphylococcus aureus* and *Staphylococcus epidermidis* are the main infectious agents. The exception is angular blepharitis, inflammation at the lateral canthus, which is often caused by *Moraxella* spp. Impetigo or erysipelas of the eyelids may be caused by *Streptococcus pyogenes*. A variety of parasitic infestations, including *Demodex folliculorum*, *Sarcoptes scabiei* (scabies), *Pediculus capitis*, and the pubic louse, *Phthirus pubis*, may involve the eyelids.[155] Infection of the lid margin is more common in adults, but may occur in children. Infections of the anterior lid margin include bacterial blepharitis, molluscum contagiosum, and parasitic diseases. Infections of the posterior lid margin include those associated with chronic meibomian gland dysfunction. Herpes simplex virus (HSV) and herpes zoster virus may involve the lid and lid margin and are discussed elsewhere in this chapter.

Anterior Eyelid Infection

Staphylococcal Blepharitis

Staphylococcal eyelid infection may be acute or chronic. Typically, the chronic form of the disease manifests as erythema and crusting of the lid margins, especially on awakening. Thickening of the lid margin is a frequent manifestation. Mild chronic conjunctival infection often occurs as a spillover by local reaction to material secreted by the infecting organism. A child with staphylococcal blepharitis may be asymptomatic or may complain of ocular discomfort or a burning, itching, or foreign body sensation. Lid hygiene measures are frequently all that is required to treat the condition, consisting of eyelid scrubs with attention given to the lid margin. Warm tap water can be used, or, in refractory cases, the eyelids and lid margins can be cleansed once or twice daily with a 50:50 mixture of baby shampoo and warm water. This mixture is applied gently with a clean washcloth. Effective lid hygiene decreases the concentration of local bacterial flora and reduces or eliminates symptoms arising from chronic staphylococcal infection. A 2- to 4-week course of topical erythromycin, bacitracin, or azithromycin ophthalmic applied twice daily to the eyelid margin may hasten resolution and reduce recurrences. Ophthalmologic ointments may cause significant temporary blurring of vision; therefore, they often are used only at night before sleeping.

Molluscum Contagiosum Infection

Molluscum contagiosum is caused by members of the family *Poxviridae*. Infection of the eyelid may be unilateral or bilateral. Infection may be transmitted by skin-to-skin contact, through fomites, or by autoinoculation.

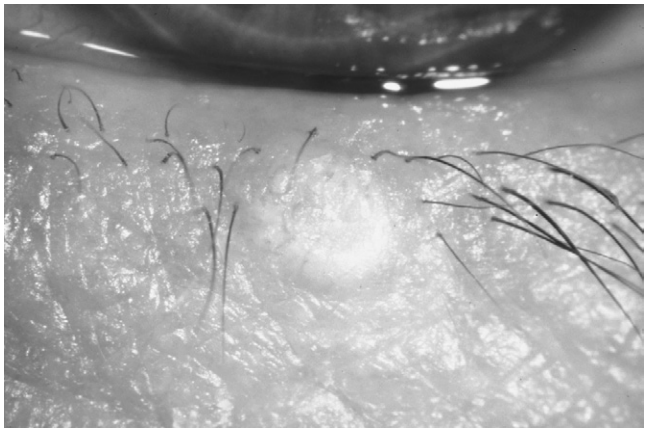

FIGURE 61-1 ■ *Molluscum contagiosum* typically is manifested as an isolated nodule or nodules approximately 1 to 3 mm in diameter. Older lesions often become umbilicated and develop a white or waxy-appearing core.

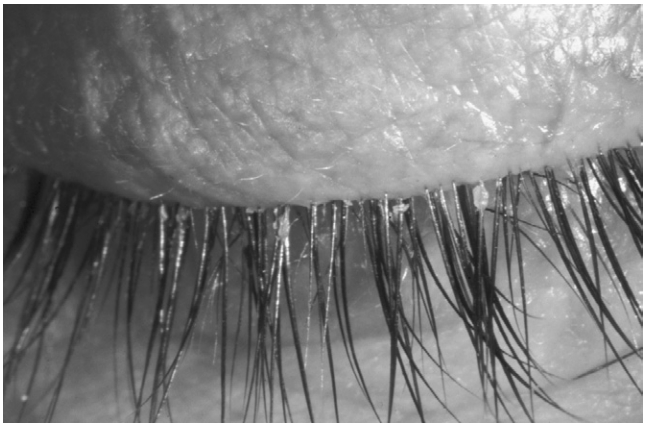

FIGURE 61-2 ■ Slit-lamp photo of *Phthirus pubis* infestation demonstrating adult lice firmly adherent to the eyelashes and egg cases (i.e., nits) attached to the proximal ends of the hair shafts.

Widespread development of lesions can occur as a result of autoinoculation. Epidemics in people who live in closed communities have been reported.[207] Eyelid manifestations typically include isolated nodules with mild surrounding inflammation (Fig. 61-1). The nodules are 1 to 3 mm in diameter. Older lesions frequently become umbilicated and develop a white or waxy-appearing core. Mild conjunctival injection frequently accompanies lesions on or near the margin of the eyelid. The associated conjunctivitis occasionally can be severe and chronic. In chronic cases, corneal epithelial disease may develop.

Molluscum infection is self-limited, with most lesions resolving spontaneously within a few months. However, the infection can be recalcitrant, especially in immunocompromised patients.[294,305] Chronic or atypical molluscum contagiosum lesions involving the eye have been reported in patients infected with human immunodeficiency virus (HIV).[183,245] In immunocompetent patients, treatment often is advocated to prevent autoinoculation, which can prolong the course of the disease. Treatment also may provide symptomatic relief. Mechanical treatment such as cryotherapy, expression or curettage of the central core, excision, and cautery may be effective.[54] Medical treatments effective against molluscum infection remote from the eye include 1 percent imiquimod cream[267] and podophyllotoxin.[266] These agents are not recommended for the treatment of periocular lesions, however, because of the possibility of injury to the eye.

Parasitic Eyelid Disease

Phthirus pubis *Infestation*

The crab louse *Phthirus pubis* is a tiny insect adapted to living in coarse, widely spaced hair. Infestation most commonly involves pubic, axillary, and body hair. The organism is transmitted by direct person-to-person contact, and perhaps by fomites.[255] Infestation of the eyelid often is a marker for sexually transmitted infections, especially in adult patients.[255] Affected patients typically have unilateral, chronic blepharoconjunctivitis; some patients may be asymptomatic. Although unmagnified ocular examination may reveal signs of the disease, diagnosis is facilitated by slit-lamp examination, which offers a magnified view of the eyelid margins and eyelashes (Fig. 61-2). Slit-lamp examination reveals adult lice firmly adherent to the eyelashes and egg cases (nits) attached to the proximal ends of the hair shafts. Reddish brown flecks of louse excreta may be found at the base of the cilia.[52] Treatment can be simple mechanical removal of the lice and nits under magnification (slit lamp or other devices.)

Medical treatment often is preferred for young children because of their inability to tolerate or permit mechanical removal. The organisms also can be smothered by the application of a bland ointment such as petrolatum jelly applied four times each day to the eyelids. Physostigmine ointment administered twice daily can be used. The agent inhibits nerve transmission in the insect and thus is directly toxic to the insect. It should be used with caution in infants and small children. If physostigmine comes into contact with the eye, it has several significant side effects, such as stimulation of accommodation, which can produce blurred distance vision that may last for several hours. Medical treatment should be continued for 2 weeks to ensure eradication of new lice that emerge from nits during the normal life cycle.[52] Lindane shampoo scrubs of the scalp, pubic hair, and body are recommended if infestation is found in these areas. Clothing and bed linen should be laundered, and family members should be examined and treated as necessary. Follow-up 4 to 6 weeks after treatment is recommended to detect reinfestation.

Demodex *Infection*

Demodex folliculorum and *Demodex brevis* are mites that frequently infest hair follicles in humans, including the hair follicles of the eyelids (Figure 61-3).[87,155] The organisms historically have been considered nonpathogenic parasites,[144] although it is thought they may cause increased hordeola formation as a result of obstruction of eyelid sebaceous glands.

Demodex is found in patients with rosacea, although a causal relationship is difficult to establish.[226] Rosacea-like

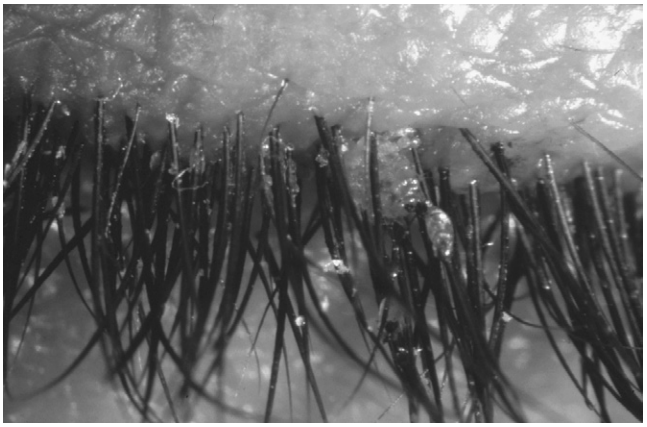

FIGURE 61-3 ■ *Demodex folliculorum* and *Demodex brevis* are mites that can infect the hair follicles of the eyelids and are found more commonly on eyelashes with cylindrical dandruff.

eruptions have been attributed to *Demodex*, and one pathologic report demonstrated a granulomatous dermal inflammation.[213] Treatment with topical pilocarpine gel may alleviate itching caused by *Demodex* infection.[97] Because of the frequency of *Demodex* infestation and the paucity of definitive disease caused by the organism, treatment often is unnecessary.

Posterior Eyelid Infection

Hordeolum

A hordeolum (i.e., stye) is an infection of the sebaceous glands in the eyelids. When the glands of Zeis are involved, the term *external hordeolum* is used. The lesion typically points to the skin surface. When the meibomian glands are involved, the term *internal hordeolum* is used. An internal hordeolum may point toward the skin or toward the palpebral conjunctiva. *S. aureus* is the most common causal agent of both internal and external hordeola.[159]

Patients with disease of the lid margin, such as those with chronic blepharitis, seborrhea, or rosacea, are prone to recurrent hordeola, especially during the first decade of life. Hordeola are manifested by erythematous, elevated, tender nodules. Nodules typically are 5 to 10 mm in diameter and usually solitary, although they may be multiple or bilateral. Patients with a history of recurrent hordeola may have them in various stages of evolution or resolution.

The lesions usually are self-limited and typically resolve within 5 to 7 days with spontaneous drainage of the abscess. Warm compresses may hasten resolution and improve comfort. Parents should be advised to place a clean washcloth soaked in warm tap water on the involved eyelid for 10 to 15 minutes several times each day. Parents should be advised to ensure that the water is not hot enough to cause a burn. For significant coexisting blepharitis, a topical antibiotic such as erythromycin ointment may prove useful by reducing the normal bacterial skin flora of the eyelid and decreasing the risk for recurrence. Systemic antibiotics rarely are indicated for acute hordeola. Children with frequent recurrences, however, may benefit from a short course of systemic antibiotics such as erythromycin (younger than 12 years) or tetracycline (older than 12 years). These agents further decrease the bacterial flora on the eyelid and may reduce the risk for recurrence even more. Lid hygiene efforts, as described for the treatment of staphylococcal blepharitis, should be instituted and maintained for children with recurrent hordeola. Surgical drainage of a hordeolum usually is unnecessary.

Chalazion

Cytologically, a chalazion may represent either a mixed-cell granulomatous inflammation or a suppurating granuloma.[69] The lesion occurs in a meibomian gland as a result of a foreign body reaction to secretions produced by the gland that have been extruded into surrounding tissue. A chalazion may develop after resolution of an internal hordeolum, in which case it is preceded by an acute stage, or it may develop primarily, without a preceding acute inflammatory phase. A typical chalazion appears as a round, nontender nodule within the substance of the eyelid. Multiple and bilateral chalazia may occur in susceptible patients. Recurrent lesions are not uncommon findings. They are typically 2 to 10 mm in diameter.[197]

Spontaneous resolution of smaller chalazia can be anticipated after a period of observation without treatment, sometimes as long as several months. Larger lesions, particularly those greater than 10 mm in diameter, frequently do not resolve without specific treatment. In patients with an acute or chronic inflammatory component, application of warm compresses may be beneficial. Surgical intervention may be warranted to treat medium to large chalazia that are cosmetically objectionable, produce astigmatism by pressing on the cornea, result in mechanical ptosis, or cause other symptoms. In rare circumstances, chalazia can result in vision loss from amblyopia.[76] The most common surgical treatment offered is incision and curettage through an internal incision on the palpebral conjunctival surface. Surgery is highly effective. It can be performed in the office, but general anesthesia is required for most young children. Because of the need for general anesthesia, we typically recommend deferring surgical treatment until several months have elapsed without spontaneous resolution. Earlier intervention may be recommended if the chalazion is particularly large, if pigmentary changes have developed in the overlying skin, or if astigmatism or ptosis is present in a young child at risk for the development of amblyopia.

Chalazia can be treated by intralesional steroid injection, surgical incision,[68] or both.[89] Dhaliwal and Bhatia[68] reported that incision plus curettage was the procedure of choice for lesions that have been present for 8.5 months or longer and for lesions 11.4 mm or larger in size, based on the results of a prospective study. The major potential drawback of intralesional steroid injection is the risk for complications developing with an otherwise relatively benign condition. Rarely, steroid injection can result in sterile abscess formation or eyelid necrosis. Intralesional

injections are done best with a chalazion clamp in place to protect the underlying globe from accidental needle trauma during injection. This device places a metal plate between the chalazion and the eye. If general anesthesia is required, incision and curettage is recommended over intralesional steroid injection.

Dacryoadenitis

Dacryoadenitis is an uncommon ophthalmic condition. Even in a busy ophthalmology practice, dacryoadenitis was diagnosed in approximately 1/10,000 patient visits.[230] The clinical manifestation is variable. Localized tenderness and swelling of the temporal aspect of the upper eyelid usually occur and often produce an "S"-shaped deformity of the lid margin. Pain is frequently a predominant feature. Associated signs and symptoms include fever, follicular conjunctivitis, mucopurulent discharge, limited extraocular movement, and proptosis.[230] Keratoconjunctivitis sicca has been reported as a consequence of Epstein-Barr virus (EBV)-associated dacryoadenitis in a child.[178]

Before the era of widespread immunization, mumps was a leading cause of dacryoadenitis. Bacteria such as staphylococci, streptococci, and gonococci also have been implicated. Exceedingly rare organisms such as *Brucella* are involved occasionally in bacterial cases.[16] EBV has been implicated as the etiologic agent in a large proportion of nonsuppurative cases. Marked regional lymphadenopathy may be a distinguishing feature of EBV dacryoadenitis.[230] Rare infectious causes include tuberculosis and Lyme disease.[198,240,243]

Appropriate laboratory evaluation includes Gram stain and culture of mucopurulent discharge from the eye. Neuroimaging is indicated when the patient has severe inflammation, proptosis, limitation of extraocular movement, or other orbital signs to rule out a more generalized orbital process. The condition easily can be confused clinically with orbital cellulitis when signs and symptoms are severe. Biopsy of the lacrimal gland may be required to confirm the diagnosis in patients not responding to standard medical treatment or when atypical features are identified on clinical examination or radiographic studies. Blood cultures are indicated for patients with signs of systemic toxicity.

Intravenous nafcillin or vancomycin is a reasonable initial antibiotic choice for severe dacryoadenitis caused by gram-positive organisms. Oral antistaphylococcal agents may be used for less severe cases. For gram-negative cases, ceftazidime or other similar agents should be considered. For suppurative cases without Gram-stain guidance, intravenous nafcillin or vancomycin should be considered as initial therapy for severe cases and oral antistaphylococcal agents for less acute cases.

Therapy in the form of warm compresses and oral analgesics is indicated for nonsuppurative dacryoadenitis. Serum testing for evidence of EBV infection should be considered in patients with regional lymphadenopathy.[230] Noninfectious causes of dacryoadenitis include sarcoidosis, Sjögren syndrome, leukemia, lymphoma, eosinophilic granuloma, autoimmune vasculitis (Churg-Strauss syndrome and Wegener granulomatosis), immunoglobulin (Ig)G4-related systemic disease, and orbital pseudotumor.[45,139,149] Noninfectious cases of dacryoadenitis sometimes can be difficult to distinguish from infectious cases. Lacrimal gland biopsy and neuroimaging usually are necessary to establish a diagnosis in noninfectious cases.[165] Intralesional steroid injection has been shown to be effective in the management of acute idiopathic dacryoadenitis; it results in marked improvement of symptoms within 7 days of treatment in most cases.[185]

Nasolacrimal Duct Obstruction

Simple membranous nasolacrimal duct obstruction occurs in an estimated 1 to 20 percent of the newborn population, and intermittent, mild, self-limited bacterial infection is a commonly associated feature.[92,110,164,200] It most commonly results from a blockage of the valve of Hasner, which is the opening from the lacrimal sac into the inferior nasal meatus. The signs of nasolacrimal duct obstruction consist of an increased tear lake, mucopurulent discharge, and epiphora. The periocular skin is sometimes mildly erythematous, with skin fissures in regions of pronounced irritation. The conjunctiva and sclera are usually white and are uninvolved. When pressure is applied over the lacrimal sac there is a reflux of mucopurulent material from the punctum.

More than 50 percent of congenital nasolacrimal duct obstructions resolve without surgical intervention.[196,211,215,221] Most cases can be observed with treatment limited to gentle lid hygiene and lacrimal sac massages. In more severe cases, medical treatment with a topical antibiotic is appropriate. The most common organisms identified in nasolacrimal duct obstruction cultures include *Streptococcus pneumoniae* and *Haemophilus influenzae*.[283] Most ophthalmologists prefer topical fluoroquinolones over aminoglycosides because they cause less ocular irritation and have better coverage of gram-positive organisms. When the condition fails to resolve, a probing procedure can be performed in the nasolacrimal duct system, which typically is successful in resolving the condition. This procedure is commonly performed in the operating room under general anesthesia but also can be performed in an office setting with child restraint when performed under 1 year of age.

Dacryocystitis

Dacryocystitis may result from congenital or acquired lacrimal outflow obstruction. More severe infection of the lacrimal sac results in dacryocystitis. This condition is manifested as acute erythema, pain, and swelling in the medial canthal region. The swelling typically is located below the medial canthal tendon. Marked epiphora generally is present, and a mucopurulent discharge frequently can be expressed through the lacrimal punctum if the proximal aspect of the lacrimal drainage system is not obstructed. If the infection has resulted in or from obstruction proximal and distal to the lacrimal sac, the overlying skin may become tense as the nasolacrimal sac distends in response to the infectious process. Formation of a fistula to the overlying skin may occur as a result of dacryocystitis, and surgical excision of the fistula tract

often is needed after the acute process has resolved. Dacryocystitis is a particularly common finding in neonates with a dacryocele, with dacryocystitis developing in as many as 60 percent of affected neonates.[212]

Aerobic and anaerobic bacteria and fungi may produce dacryocystitis.[34,36] In one study, *S. epidermidis* and *Pseudomonas* spp. were the aerobic organisms identified most frequently, and *Peptostreptococcus* spp. and *Propionibacterium* spp. were the anaerobes isolated most frequently. Less common agents include *Escherichia coli*, *Pseudomonas* spp., *H. influenzae*, *Pasteurella multocida*, and various anaerobes. Laboratory investigation should include aerobic and anaerobic culture of mucopurulent discharge from the lacrimal sac. Mild massage of the lacrimal sac may be used to facilitate expression of material for Gram stain and culture. A sepsis workup should be considered for children who are acutely ill and for young infants.

Intravenous nafcillin, vancomycin, or both are good initial therapeutic choices for serious gram-positive infections. Mild cases in older children can be treated with oral antibiotics. Intravenous ceftazidime is a reasonable initial antibiotic choice for gram-negative dacryocystitis. Oral ciprofloxacin is useful for less severe cases in adult patients, although the drug is not approved for use in children. Intravenous nafcillin or vancomycin typically provides good initial empirical therapy in patients when Gram-stain guidance is not available.

Ophthalmologic consultation should be requested in all cases of acute dacryocystitis. Decompression of the lacrimal sac by aspiration, incision, and drainage, or probing the proximal lacrimal drainage system may be needed to hasten resolution. Probing of the distal lacrimal system often is deferred until the acute infection has subsided, although probing during the acute infection has been reported to be a safe and effective adjunct to treatment.[219] Mucopurulent material obtained during surgical decompression should be sent for appropriate culture.

Preseptal (Periorbital) Cellulitis

The term *preseptal cellulitis* refers to an infectious process in the eyelids that is isolated to regions anterior to the orbital septum. The orbital septum is a thin layer of fascia that extends vertically from the periosteum of the orbital rim to the tarsal plate within the eyelids. Although it is penetrated by nerves and vascular structures, the septum provides a barrier that slows the spread of infectious agents into deeper orbital and retro-orbital structures.[262] Typical signs and symptoms of preseptal cellulitis include erythema and edema of the eyelids. Distinctively absent are signs of deeper orbital involvement such as restricted ocular motility, pain with eye movement, and proptosis. Preseptal cellulitis may occur after trauma or be caused by spread of infection from adjacent structures, such as skin and the upper respiratory system.[292]

Posttraumatic Preseptal Cellulitis

Posttraumatic preseptal cellulitis occurs after puncture wounds on the lids, face, or scalp. It also may occur after blunt trauma with no obvious entry wound. The etiologic agents most commonly identified are *S. aureus* and *S. pyogenes*, and polymicrobial infections can occur. Other bacterial causes include non–spore-forming anaerobes such as *Peptococcus*, *Peptostreptococcus*, and *Bacteroides*. Infection by aerobic gram-negative bacilli is an uncommon finding.[13] *P. multocida* is a common organism that produces posttraumatic preseptal cellulitis after dog and cat bites.[154,158] Cellulitis secondary to methicillin-resistant *S. aureus* (MRSA) is increasing in frequency and is a common cause of community-acquired cellulitis in some locations.

Clinical signs and symptoms are determined in large part by the severity of the injury, the interval since injury, and the infecting organisms. The involved lids are edematous, erythematous, and typically quite tender. Fluctuation of subcutaneous tissue may be seen if an abscess has developed. Swelling of the uninvolved contralateral eyelids may occur as a result of lymphedema. As with any form of isolated preseptal cellulitis, vision is unaffected and proptosis and eye movement disturbances are absent. On rare occasions, eyelid edema may be sufficiently severe to preclude adequate evaluation of the eye. Neuroimaging is required in such cases to assess the globe and rule out involvement of structures posterior to the orbital septum. Ophthalmologic consultation is critical in cases of severe posttraumatic preseptal cellulitis because of the potential for concurrent globe injury.

Laboratory analysis includes Gram stain and aerobic and anaerobic culture of mucopurulent material to aid in therapeutic decisions. Amoxicillin-clavulanate or a related agent is the drug of choice for treating posttraumatic cellulitis caused by a dog bite because of the high prevalence of *P. multocida*. Tetanus prophylaxis should be guided by standard recommendations. Surgical drainage of large abscesses may be required if a rapid response to antimicrobial therapy does not occur.

Nontraumatic Preseptal Cellulitis

The clinical features of nonsuppurative, nontraumatic preseptal cellulitis depend to a large degree on the causative agent. Erythema and swelling of the involved eyelids are typical and often are accompanied by pain. Signs of orbital infection, such as altered vision, proptosis, and eye movement abnormalities, are absent.

Before the advent of *H. influenzae* type b vaccine, this organism frequently was a cause of nonsuppurative preseptal cellulitis in children. *H. influenzae* type b is seen infrequently as a cause of preseptal cellulitis today.[73] It was a particularly dangerous agent because of a high risk for spread to the central nervous system (CNS), which occurred in as many as 2 to 3 percent of patients. Although rare today, *H. influenzae* type b infections still may be encountered. Like many infecting organisms, it gains access to subcutaneous tissue through infected nasal passages.

S. pneumoniae is now the most common bacterial cause of preseptal cellulitis in the pediatric age group.[73] It occurs in association with upper respiratory tract infection, although constitutional symptoms usually are less pronounced than those associated with *H. influenzae* type b infection. A variety of other bacterial agents may cause preseptal cellulitis, but they are seen less commonly.

Preseptal cellulitis occasionally has been reported to be due to a variety of other organisms, including *Trichophyton* (ringworm),[286] tuberculosis,[224] and anthrax.[9,41]

Adenovirus is another particularly common cause of preseptal cellulitis in children. Adenovirus is an important consideration in the differential diagnosis of childhood preseptal cellulitis because, despite being self-limited, the condition can occasionally mimic bacterial infection and prompt unnecessary treatment with antibiotics. Adenovirus can be recognized by its characteristic copious discharge, which may be serous. Swelling of the lid may be prominent, but erythema usually is minimal. Preauricular lymphadenopathy often occurs in older children, and marked conjunctival hyperemia with or without chemosis and subconjunctival hemorrhage may be present. Photophobia also may be noticed in cases of concurrent punctate keratopathy. A history of recent contact with other infected individuals frequently is noted and should be sought. Care should be taken to avoid spreading infection to family members, medical personnel, and others.

Hospital admission should be considered for children younger than 1 year of age with bacterial preseptal cellulitis. Hospitalization also is important for children with signs of systemic toxicity and those with inadequate *H. influenzae* immunization. A sepsis workup is indicated for children with signs of systemic toxicity and for extremely young children. Ophthalmologic consultation is recommended if orbital involvement is suspected or if clinical examination is inconclusive. Computed tomography (CT) usually is unnecessary for isolated preseptal cellulitis. Cultures of blood obtained from patients with preseptal cellulitis generally are negative but are more likely to be positive in children younger than 2 years. Culture of conjunctival discharge is done often but rarely has significant diagnostic benefit.

A severity index for scoring preseptal cellulitis in children has been reported to help guide treatment decisions.[289]

Antibacterial treatment should include intravenous agents for infants and those with signs of serious systemic infection. Intravenous cefuroxime or a combination of nafcillin plus cefotaxime or ceftriaxone frequently is recommended for empirical therapy. When MRSA preseptal cellulitis is suspected because of poor response to treatment or through cultures, clindamycin and trimethoprim-sulfamethoxazole are often the first-line agents. In situations in which MRSA preseptal cellulitis does not respond favorably to these medications, vancomycin or linezolid with rifampin may be effective treatments.[11,261] Outpatient treatment with intramuscular or oral antibiotics is reasonable for older, less acutely ill children. Intracranial infection has been associated with preseptal cellulitis in pediatric patients. Intracranial involvement should be suspected in any patient 7 years of age or older with preseptal or orbital cellulitis associated with an orbital subperiosteal abscess, Pott puffy tumor, concurrent sinusitis, complaints of headache, and persistent fever despite intravenous antibiotics.[229]

Systemic antibiotics should be continued for 7 to 10 days. Patients in whom intravenous antibiotics are started initially can switch to an oral antibiotic after they have been afebrile for at least 24 hours and otherwise have improved clinically, unless the possibility of development of sepsis or meningitis remains a concern. When antibiotic treatment fails, other noninfectious causes should be explored. Reports exist of conditions such as Langerhans histiocytosis, lipoblastomatosis, and dermoid cysts that can mimic preseptal cellulitis.[72,79,145]

Orbital Cellulitis

Bacterial infection of orbital structures posterior to the orbital septum is the most frequent cause of acute orbital inflammation. Orbital cellulitis occurs more commonly in children and more frequently during cold weather, when sinusitis is more prevalent.

Initial signs and symptoms can vary from mild inflammation to severe and fulminant orbital disease. Cardinal signs and symptoms of infectious orbital cellulitis include proptosis, limited eye movement (including total ophthalmoplegia), pain with eye movement, and an abnormal pupillary response. Decreased vision or even blindness can occur as the most serious ophthalmic complication.[239] Death can result from intracranial extension of the infection if appropriate treatment is not initiated. Elevated intraocular pressure and chemosis of the conjunctiva are common ancillary signs. Preseptal cellulitis often coexists with orbital cellulitis but is not a prerequisite.

Most cases of orbital cellulitis are caused by spread of infection from an adjacent infected sinus.[47,191] Ethmoid sinusitis is the most common predisposing factor.[184] Rare cases are due to penetrating orbital trauma or skin infection involving the face, with spread of organisms into the orbit. Orbital cellulitis may occur infrequently after orbital, ocular, or periocular surgery.[7,209,300] Orbital cellulitis and cavernous sinus thrombosis have been reported to occur after dental infections and dental surgery.[38]

Comprehensive evaluation of a patient with confirmed or suspected orbital cellulitis includes ophthalmologic and systemic examination. Assessment of visual acuity individually in each eye is important for excluding vision loss and establishing a baseline to aid in monitoring progression of the disease or the effects of therapy. Evaluation of optic nerve dysfunction by examining the pupils for an afferent pupillary defect (APD) is important before pupillary dilation is performed to assess the retina. Careful evaluation of extraocular movement should be performed in all extreme positions of gaze to identify limitation of ocular duction and elicit pain on eye movement. The presence or absence of proptosis can be assessed clinically by viewing the eyes from above (bird's-eye view) or below (worm's-eye view) and by comparing their relative positions within the orbits. In severe cases of orbital cellulitis, funduscopic examination may reveal dilation of the retinal venules and signs of compressive optic neuropathy, such as optic disk edema. In severe cases central retinal artery and vein occlusion has been reported.[58,135,205] Systemic evaluation includes determination of temperature, which usually is in the range of 39° to 40° C (102° to 104° F). Sinus examination, a screening neurologic examination, and evaluation for signs and symptoms of sepsis and meningitis should be performed.

In any case of clinically definite or suspected orbital cellulitis, CT of the orbit and brain is essential. CT can establish or confirm the diagnosis of orbital cellulitis and provides critical information needed to manage the patient. Imaging of the brain is important because orbital cellulitis can evolve into a brain abscess, meningitis, or cavernous sinus thrombosis. However, when a clinical response to treatment is noted, improvement in CT findings frequently is delayed. Therefore, recurrent CT scanning of a child with clinically improving findings is not indicated unless new signs or symptoms of concern develop.

Microbiologic studies often are acutely unhelpful for the routine patient with orbital cellulitis. Nonetheless, baseline studies remain important because critical information sometimes is acquired. Blood culture samples should be obtained at a minimum, and a lumbar puncture with culture of cerebrospinal fluid (CSF) should be considered in infants and those with signs of CNS infection. Culture of the ocular, nasal, and nasopharyngeal mucous membranes is of limited value and can be omitted. However, if surgical drainage is performed, samples of any material removed should be obtained for culture.

Optimal management of a child with orbital cellulitis requires a multidisciplinary approach. In addition to evaluation and management by an experienced pediatrician, ophthalmologic and otolaryngologic consultation should be obtained. Neurosurgical consultation is required when involvement of the CNS is diagnosed or suspected. In atypical cases and those not responding to treatment, consultation with an infectious disease specialist is warranted.

The most common offending etiologic bacteria are *S. aureus*, *Streptococcus* spp., and *Haemophilus* spp. (other than *H. influenzae*).[177] *S. pneumoniae* also is implicated frequently, and a variety of less common organisms have been reported. *H. influenzae* orbital cellulitis rarely has occurred since widespread use of the *H. influenzae* type b vaccine was implemented.[3,73] Fungal infection of the orbit occasionally is encountered, typically in immunocompromised individuals.[175]

The differential diagnosis of orbital inflammation in children includes a broad range of noninfectious conditions, including blunt trauma, cavernous sinus thrombosis, idiopathic inflammatory orbital pseudotumor, Wegener granulomatosis, sarcoidosis, leukemic infiltration, lymphoma, rhabdomyosarcoma, necrotic retinoblastoma, metastatic carcinoma, and histiocytosis X. Thyroid ophthalmopathy also can be manifested as an acute orbital inflammatory process, although usually its onset is slow and insidious.

Treatment of all patients with orbital cellulitis requires hospitalization and initiation of intravenous antibiotics as soon as possible. Infection with penicillin-resistant organisms is an increasingly common occurrence and must be considered during treatment.[43,257] Appropriate initial antibiotic therapy may include nafcillin, metronidazole, and cefotaxime as combination therapy. Given the increasing incidence of MRSA, initial treatment with vancomycin or clindamycin should be considered.[51,238,248] Other antimicrobial agents may be useful, and local susceptibility patterns should guide the choice of initial antimicrobial therapy. Antibiotic coverage should be modified according to the clinical course and culture results. If the patient fails to respond to antibiotic treatment within 24 to 48 hours, consultation with an infectious disease specialist and repeat CT to look for the development of an orbital abscess should be considered (Fig. 61-4). The mean hospital stay for uncomplicated cases of orbital cellulitis is 10 to 14 days, and oral antibiotics should be prescribed for 7 to 10 days after discharge. When the source of infection is believed to be from sinusitis, a nasal decongestant is commonly prescribed to aid in opening the sinus ostia, promoting drainage of the infected sinus, and speeding resolution. Nasal decongestants should be continued for 7 to 10 days after initiation.

FIGURE 61-4 ■ Failure of response of orbital cellulitis to antibiotic treatment may be a sign of development of a subperiosteal orbital abscess (seen here in the right medial orbit).

Although treatment of orbital cellulitis with steroids remains controversial, their use in the treatment of acute and chronic sinusitis has become increasingly common. Studies have shown that steroids can reduce levels of inflammatory cytokines in the sinonasal mucosa of individuals with sinusitis.[40,291] In a study on the use of steroids in children with orbital cellulitis, Yen and Yen[303] reported no adverse effects of this adjunct treatment with systemic antibiotics. Prospective studies on the use of steroids in orbital cellulitis have been proposed to determine whether they have any clinical benefit.

Children with orbital cellulitis require diligent follow-up while in the hospital. Vision should be assessed at the bedside daily; results may be more accurate if a single examiner routinely assesses vision for a given patient. Pupillary examination for an APD should be performed at each examination. Development of an APD indicates compromise of the optic nerve, warrants escalation of treatment, and usually requires urgent surgical

intervention. Reduction of vision, development of an APD, onset of CNS signs, or worsening of systemic status should prompt emergency repeat neuroimaging of the brain and orbit, with further intervention as dictated by results of the scan. The close anatomic relationship of the orbit to the brain, with the orbital venous system freely anastomosing with the facial venous plexus and cranial venous sinus system through a series of valveless veins, seriously increases the potential for spread of infection to contiguous structures, including the brain.

Acute surgical intervention to decompress the orbit or drain an orbital or subperiosteal abscess is indicated if vision loss or an APD is identified at any point during treatment. Immediate neurosurgical consideration is indicated if CNS involvement is documented. Most patients without evidence of vision loss, optic nerve dysfunction, or CNS involvement can be managed successfully medically. The surgical adage that all abscesses should be subjected to incision and drainage does not apply to abscesses associated with orbital cellulitis. Most subperiosteal abscesses located in the medial orbit can be managed successfully with medical therapy alone.[108,236] Formation of an abscess within the substance of the orbit (as opposed to a subperiosteal abscess) seldom occurs. Guidelines for surgical drainage are similar to those for subperiosteal abscess,[236] although such abscesses are more likely to require surgical intervention because of treatment failure or spread of infection to contiguous structures.[108] Provided that clinical improvement continues, no worrisome signs or symptoms of CNS involvement develop, and the patient's overall clinical status does not worsen, repeat neuroimaging of patients with an orbital abscess is unnecessary. Short-term resolution of an orbital abscess often is not obvious on CT. The radiographic appearance of the abscess typically remains unchanged on early follow-up scans, although it may no longer contain viable organisms.

Sinus drainage by an otolaryngologist frequently is required to hasten resolution. Formation of an abscess is not a prerequisite for surgical intervention, and orbital cellulitis without abscess formation may progress to the point of requiring surgery. Despite prompt and appropriate treatment, serious complications such as permanent vision loss and brain abscess can occur.[35,64,118,229,239] Most patients, however, can be treated effectively with no permanent sequelae.

Orbital cellulitis caused by fungal infection has a course and prognosis markedly different from those of bacterial orbital cellulitis, particularly cellulitis caused by mucormycosis and aspergillosis. Fungal orbital cellulitis typically occurs in patients who are immunocompromised or patients with metabolic acidosis, such as those with poorly controlled diabetes. It may be manifested as a subacute or chronic process. Orbital apex syndrome is considered to be the most severe form, with loss of function of all cranial nerves traversing the orbital apex into the orbit (i.e., cranial nerves II, III, IV, V, and VI). A black eschar-like lesion may form in the oropharynx or nasopharynx in cases of fungal infection.

Aspergillus orbital infections (most commonly caused by *Aspergillus flavus*, *Aspergillus fumigatus*, or *Aspergillus oryzae*) are rare findings in children and may take a slow, chronic course over a period of months or years. No clear predisposing factors exist, but it has a predilection for humid climates and most cases occur in otherwise healthy individuals. Signs and symptoms of orbital infection caused by *Aspergillus* spp. include loss of vision, constant dull pain, decreased or absent ocular motility, and proptosis with firm resistance to retropulsion. Palate and nasopharyngeal lesions occur but are rare. Biopsy is required for establishing the diagnosis.[107]

Effective treatment of orbital fungal infection requires correction of systemic and metabolic disturbances and administration of intravenous antifungal agents such as amphotericin B. Posaconazole has been shown to be effective as an alternative treatment in those who fail to respond to or cannot tolerate treatment with amphotericin B.[237] Surgical débridement of the orbit or adjacent infected sinuses frequently is required. Treatment often is unsuccessful, and fatalities are not uncommon, particularly with mucormycosis.

The larva of *Echinococcus granulosus* can produce a hydatid cyst in the orbit. The dog is the definitive host animal, although the organism also may live in the intestines of sheep, goats, cattle, pigs, and other animals. The disease is endemic in the Middle East, Africa, and Asia. Humans become infected by eating contaminated food, typically meat, and infection may occur in any age group. Affected patients have noninflammatory proptosis, decreased ocular motility, and dull orbital pain. Surgical excision is required for treatment. The cyst may be injected with hypertonic saline to kill the parasite, followed by excision.[105]

CONJUNCTIVAL INFECTIONS

The conjunctiva is the highly modified and specialized mucous membrane covering the inner surfaces of the eyelids and the anterior surface of the globe. The part that lines the inner surface of the eyelids is the *palpebral conjunctiva*, and the part covering the globe is the *bulbar conjunctiva*. The conjunctiva contains numerous small glands that produce two of the three parts of the tear film—a lower mucous layer acting as a wetting agent and a middle aqueous layer that makes up the bulk of the tear film; the third layer is oily and is produced by the sebaceous and meibomian glands of the eyelid and prevents rapid evaporation. The conjunctiva can be infected by many bacteria and viruses, and by noninfectious allergic and toxic agents.

Conjunctivitis can cause mild or significant symptoms—burning, itching, or a foreign body sensation. Itching commonly signifies an allergic or viral cause. The conjunctival redness (injection and erythema) of infectious conjunctivitis is usually more severe located away from the edge of the cornea, whereas conjunctival injection concentrated adjacent to the cornea (limbal, or ciliary flush) suggests inflammation of the cornea (keratitis), inflammation of the iris (iritis), inflammation of the iris and ciliary body (iridocyclitis), or occasionally glaucoma or a corneal foreign body. When the eye is very severely infected, however, it may be so intensely red that such a differentiating pattern is not discernible.

Conjunctivitis is often accompanied by a discharge with important diagnostic properties. Purulence suggests a bacterial cause, a mucoid discharge suggests a viral infection, and a serous discharge may be seen with viral or allergic causes. Patients with isolated conjunctivitis usually do not have significant blurring of the vision. Apparent conjunctivitis with poor vision warrants a search for another diagnosis.[101,174] A (very) general rule is red eye with good vision: probably conjunctivitis; red eye with bad vision: probably *not* conjunctivitis.[217]

Bacterial Conjunctivitis

Bacterial conjunctivitis is the most common form of infectious conjunctivitis in children. It is characterized by a purulent discharge and can be unilateral or bilateral. It is useful clinically to divide bacterial conjunctivitis into mild and severe forms because the treatments are different.[104,128]

Mild Bacterial Conjunctivitis

The agents most commonly causing mild bacterial conjunctivitis in children 5 years of age or older are *S. pneumoniae* and *Moraxella* spp.[101] *H. influenzae* was a prominent causative agent before the availability of *H. influenzae* type b vaccine. *S. aureus* conjunctivitis is seen most frequently after trauma or surgical manipulation. Conjunctival stains and cultures are usually not necessary, because the disease is almost invariably self-limited or responds rapidly to topical antibiotics.

Many topical antimicrobial agents for bacterial conjunctivitis are readily available, and include moxifloxacin, gatifloxacin, ciprofloxacin, ofloxacin, norfloxacin, tobramycin, gentamicin, erythromycin, sulfacetamide, and various combinations. Aminoglycoside-containing compounds such as neomycin can occasionally cause a dramatic allergic blepharoconjunctivitis that is worse than the original disease. The choice of using either drops or ointment is best left to the person who will be instilling the medication, because neither has any proven therapeutic advantage. With the emergence of multidrug-resistant organisms, the choice of antibiotic should be modified accordingly. Newer agents, such as the fourth-generation fluoroquinolones (moxifloxacin and gatifloxacin), have many advantages over older drugs, including broad-spectrum coverage, ease of dosing, and pH neutrality. A typical regimen for treatment of mild conjunctivitis is 1 drop or a ¼-inch bead of ointment placed into the inferior conjunctival fornix three to six times daily for 5 to 7 days, depending on the medication. Persistent infection calls for a prompt return to the physician for reconsideration of the diagnosis. Mild bacterial conjunctivitis generally resolves spontaneously in 7 to 14 days without treatment.[100,104]

Severe Bacterial Conjunctivitis

Severe bacterial conjunctivitis, characterized by ocular discomfort, pronounced redness, and copious purulent discharge, is usually caused by *Neisseria gonorrhoeae*, *Neisseria meningitidis*, *S. aureus*, *S. pneumoniae*, and, in children younger than 5 years, *H. influenzae*. A hyperpurulent state in which the copious purulent discharge reaccumulates in a matter of minutes is characteristic of infection with *N. gonorrhoeae*.[117,258] Severe conjunctivitis calls for stains and cultures. Samples from both eyes should be stained and cultured separately, even if only one eye is involved, to allow the uninvolved eye to serve as a control.[269] Gram stains of conjunctival scrapings should be done at the time of culture. A useful culture technique includes the use of a cotton or calcium alginate swab (e.g., Calgiswab, Spectrum, or Houston) gently rubbed against the palpebral conjunctiva of the lower lid and inoculated onto blood and chocolate agar. If *N. gonorrhoeae* is suspected, a culture for chlamydia is also indicated, because concurrent infection with both organisms is common.[250,253]

The treatment of severe bacterial conjunctivitis is based initially on the results of the stains and later modified according to cultures and sensitivities. If *Neisseria* is strongly suspected, the patient should be treated for *Neisseria*, even if the laboratory results are not confirmatory. Ocular *N. gonorrhoeae* infection is a vision-threatening and life-threatening disease. This organism can penetrate the intact cornea and cause microbial keratitis (i.e., infection of the cornea), corneal perforation, and endophthalmitis (i.e., infection inside the eyeball), in addition to the conjunctivitis. *N. gonorrhoeae* conjunctivitis should be considered in three patient groups: neonates after passage through an infected birth canal, sexually active individuals, and possible victims of sexual abuse. Pediatric infection with *N. gonorrhoeae* requires hospital admission and administration of a systemic antibiotic. Because of the prevalence of penicillin-resistant strains, a broad-spectrum (third-generation) cephalosporin, such as ceftriaxone, is the most appropriate choice of antibiotic.[113] Adjunctive treatment of *N. gonorrhoeae* conjunctivitis with topical moxifloxacin and simple saline irrigation for 5 days can be helpful, but topical agents should never be used as isolated treatment.[117] Moxifloxacin is a particularly good antibiotic choice because it is effective against chlamydia, as well.

Conjunctivitis caused by gram-positive cocci can be treated with topical moxifloxacin, gatifloxacin, ciprofloxacin, or erythromycin. Systemic nafcillin, a second- or third-generation cephalosporin, or both can be added as needed for more extensive infections. Gram-negative bacterial conjunctivitis can be treated with topical erythromycin ointment or an aminoglycoside drip such as gentamicin or tobramycin. Systemic antibiotics can be added if needed.[269]

Viral Conjunctivitis

Adenoviral Conjunctivitis

Viruses are another common cause of infectious conjunctivitis in children. Many pediatric cases of viral conjunctivitis are caused by adenovirus. Serotypes 1, 2, 3, 4, 7, and 10 produce an acute form of conjunctivitis with prominent conjunctival follicles. Serotypes 3 and 7 also

may cause pharyngoconjunctival fever. This entity is characterized by conjunctivitis, fever, and pharyngitis.[25] Serotypes 8, 19, and 37 can cause epidemic keratoconjunctivitis.[269] The keratitis is characterized by a combination of a punctate epithelial keratitis (best viewed by slit-lamp examination) and an immune response that results in subepithelial (i.e., in the corneal stroma) infiltrates. Photophobia is a prominent feature of this condition, and visual acuity may be markedly decreased. Epidemic keratoconjunctivitis is often associated with pharyngitis and rhinitis, which may precede or be concurrent with the conjunctivitis.

Adenoviral conjunctivitis may be highly contagious. It is transmitted easily from an infected individual to others at home or at school. The incubation period is 5 to 10 days but may be as long as 21 days. The virus is shed from the infected conjunctiva for 7 to 12 days after the onset of infection. Frequently, a prodromal upper respiratory tract infection consisting of fever, pharyngitis, or otitis media occurs.[269] Ocular signs and symptoms include photophobia (with corneal involvement), foreign body sensation, epiphora (tearing), bulbar and palpebral conjunctival injection and chemosis (edema of the conjunctiva), and subconjunctival hemorrhage.[121] Formation of grayish-pink friable membranes on the palpebral conjunctiva is a hallmark of the disease and may result in bleeding when removed. Preauricular lymphadenopathy is a common feature in older children and adults. Keratitis may be prolonged, with mild to moderate reduction of vision lasting weeks to months.[121,173]

The diagnosis of adenoviral conjunctivitis is almost always clinical only. Only rarely is laboratory confirmation necessary. Viral cultures are possible when indicated, and a rapid enzyme immunoassay test is available.[296] Treatment of adenoviral conjunctivitis is supportive, aimed at decreasing the symptoms of irritation, photophobia, and blurred vision. Cool compresses and acetaminophen are helpful; removal of conjunctival membranes with a moistened cotton swab may relieve the foreign-body sensation. A small amount of bleeding often occurs after removal of the membranes, and they can recur after several days. If corneal subepithelial infiltrates cause significant discomfort or an unacceptable decrease in vision, treatment with a short course of topical steroids may provide symptomatic relief and speed resolution. The use of steroid preparations requires careful monitoring,[173,269] and they should be prescribed only by an ophthalmologist.[143,254]

The clinician should wear gloves when examining patients with suspected adenovirus infection. Careful hand washing is essential after direct contact. Instruments or equipment used in examining an infected patient should be cleaned with 10 percent sodium hypochlorite solution or other solutions known to eradicate the adenovirus.

Mini-epidemics of adenovirus-related conjunctivitis can originate in physicians' offices.[13,98] At home, families should exercise caution, and separate the towels and bed clothes of the patient from those of others in the household. Children of school age should be kept at home for 7 days or longer to reduce the risk for transmitting the infection to classmates.[269]

Herpes Simplex Virus Conjunctivitis and Complex Forms

HSV conjunctivitis may occur as a primary or secondary infection. Ocular infection usually is caused by HSV-1, except in newborns, in whom HSV-2 predominates.[49] Typical initial signs of HSV conjunctivitis include a serous discharge, scant conjunctival follicle formation on the inferior palpebral conjunctiva, and preauricular lymphadenopathy.[306] Eighty percent of cases are unilateral. Eyelid vesicles often occur in primary infections. Bulbar conjunctival ulceration is an unusual occurrence, but when present, it is virtually pathognomonic of primary HSV-1 infection. Keratitis occurs in as many as 50 percent of primary cases and is characterized by mild epithelial irregularities. Dendrites (branch-shaped lesions of the corneal epithelium) can occur in primary infections, but reactivated HSV keratitis frequently exhibits the characteristic dendritic pattern. Lid vesicles usually do not develop in cases of reactivated HSV infection.[142]

Primary HSV dermatoblepharitis is seen most commonly in children younger than 6 years, but it may occur at any age. The initial episode may be associated with an upper respiratory tract infection, and recurrences are common. Clinical signs include eyelid vesicular reaction, mild follicular conjunctivitis, preauricular lymphadenopathy, and, occasionally, atypical epithelial keratitis. Secondary bacterial infection can occur. Systemic acyclovir is a safe and effective treatment, although the disease itself typically is self-limited and does not require treatment.[142]

The diagnosis of HSV keratoconjunctivitis usually is made on the basis of the clinical appearance alone. Antigen detection tests or viral cultures can be used when the diagnosis is in question.[137] Viral cultures, when necessary, require special handling.[269] In culturing primary HSV cases, the skin surface is swabbed with an alcohol sponge, and a tuberculin syringe with a 30-gauge needle is used to aspirate fluid from an intact vesicle. If no vesicles are present, a Dacron swab is wiped on the palpebral conjunctiva of the lower lid. The viral transport medium is inoculated and taken to the laboratory for special handling.

Treatment of HSV conjunctivitis alone (in the absence of corneal epithelial disease) is controversial. Oral acyclovir may be used for severe cases of primary HSV infection.[246,265] Three topical antiviral agents are available: iododeoxyuridine, vidarabine, and trifluridine.

When epithelial HSV keratitis is reactivated and the typical dendritic (branched) epithelial lesions are seen, the cornea usually is hypoesthetic. Iritis may be associated with HSV keratitis and is characterized by miosis, photophobia, ocular pain, and foreign-body sensation. Vision may be decreased if the epithelial disease involves the visual axis.[269] Epithelial HSV may be atypical, may be more severe, and may be more complicated in patients receiving topical steroids and in immunocompromised patients.

Treatment with topical trifluridine or vidarabine is indicated in all cases of HSV keratitis. Topical steroids

are effective in decreasing corneal scarring caused by HSV stromal, but should be used by an ophthalmologist only. When using a topical steroid, coverage with a topical antiviral agent such as vidarabine always should be included to reduce the risk for recurrent active viral proliferation. Oral acyclovir is not effective for treating active HSV keratitis, but it may be useful in treating HSV uveitis.[269] Ancillary treatments include cycloplegic eye drops to dilate the pupil and pain medications as needed.

Although not helpful in treating acute epithelial disease, chronic suppression with oral acyclovir is effective in reducing the number of recurrences of HSV epithelial and stromal keratitis, especially in patients with stromal keratitis.[265,269] Interferon also significantly adds to the efficacy of topical antiviral therapy, but the adverse side effects of interferon must be weighed against its potential benefits.[265]

External Ocular Infections with Varicella-Zoster Virus

Childhood varicella infection (chickenpox) commonly is accompanied by conjunctivitis. Vesicles, ulcers, or both occur occasionally on the bulbar or palpebral conjunctiva. Conjunctivitis associated with varicella infection does not result in permanent visual sequelae. Corneal involvement rarely occurs and typically heals without sequelae. Occasionally, it may result in stromal scarring and produce irregular astigmatism and reduced vision.

After primary varicella infection occurs, the virus may persist in latent form in the trigeminal nerve ganglia. Herpes zoster ophthalmicus occurs when the ophthalmic division of the trigeminal nerve is affected by reactivation of the virus. The condition occurs more commonly in immunocompromised patients, and recurrences occur infrequently except in these patients.

The diagnosis of herpes zoster ophthalmicus is almost always made on the basis of the characteristic clinical feature of a painful, tender vesicular eruption of one V-1 dermatome. Ocular involvement may include keratitis and uveitis. Corneal epithelial lesions may appear dendritiform, with or without subepithelial infiltrates. Uveitis may occur with or without associated keratitis. Usually the uveitis is mild, but occasionally it may be severe, especially in immunocompromised patients, with the formation of a hypopyon (pus in the anterior chamber) or a hyphema. Immunofluorescence testing of vesicular base scrapings or viral cultures may be helpful if the manifestation is atypical or the diagnosis is in doubt.[156]

Treatment of herpes zoster ophthalmicus involves the administration of oral or intravenous acyclovir. Treatment is most effective when initiated within 72 hours of the appearance of vesicles. The keratitis and uveitis do not respond to topical antiviral therapy.[67] Occasionally, topical steroids may be helpful in treating varicella keratitis and uveitis, but such treatment should be administered under the direction of an ophthalmologist.[173]

Chlamydial Conjunctivitis and Trachoma

Chlamydia spp. can cause conjunctivitis and trachoma. *Chlamydia psittaci* rarely causes ocular disease in humans. *Chlamydia trachomatis*, however, has numerous serotypes that affect the eye. Serotypes A, B, Ba, and C cause trachoma, and serotypes B, C, D, Da, D–, E, F, G, H, I, Ia, J, and K cause inclusion conjunctivitis, including neonatal inclusion conjunctivitis. Neonatal chlamydial conjunctivitis is addressed in the discussion of neonatal conjunctivitis. Inclusion conjunctivitis in older children and adults is a subacute or chronic inflammation of the conjunctiva. The condition may be unilateral or bilateral. A mucopurulent discharge typically occurs, as do follicles on the bulbar and perilimbal conjunctiva. Preauricular lymphadenopathy is a common feature. Punctate epithelial keratitis with subepithelial infiltrates and a superior micropannus (i.e., vascular growth on the upper edge of the cornea) may develop.[61]

The differential diagnosis of inclusion conjunctivitis includes viral and bacterial conjunctivitis, molluscum contagiosum, and toxic keratoconjunctivitis from chronic administration of topical agents. Laboratory testing may be necessary to confirm the diagnosis. Giemsa staining of conjunctival scrapings may demonstrate the classic intracytoplasmic inclusions. A fluorescent antibody detection test or an enzyme immunoassay can be used for a rapid diagnosis.[269] Chlamydial cultures may be needed when the diagnosis remains in doubt.

Treatment consists of oral erythromycin or doxycycline if systemic infection is suspected. Topical erythromycin or tetracycline alone four times each day for 7 days is effective treatment of infection limited to the conjunctiva.[61,269] Moxifloxacin has been shown to be effective against chlamydia but is not yet the recommended treatment of choice.

Trachoma, a chronic blinding conjunctivitis, remains a prominent etiology of blindness worldwide, ranking 6th overall, causing 4 percent of all blindness. It is a disease of impoverished populations that is exacerbated by inadequate supplies of water and poor hygiene and sanitation. Trachoma seldom is seen in fully developed countries. In the United States, it is encountered on Native American reservations in the Southwest and in individuals from endemic foreign areas. Eye-seeking flies play an important role in transmission of *Chlamydia* from one person to another.[269]

Trachoma causes blindness by producing chronic inflammation of the palpebral conjunctiva of the upper eyelid with secondary scar formation. Contracture of the scars cause entropion of the eyelid and trichiasis (cilia rubbing on the cornea). After many years of infection and reinfection this leads to corneal neovascularization, opacification, and vision loss.[268,279] Less commonly, the cornea may be infected directly. The complete course of the disease from initial infection to blindness generally takes decades. Children do not become blind from trachoma, but they are the most significant constant chronic reservoir of the disease.

The diagnosis of trachoma usually is made on the basis of clinical findings alone. The disease passes through characteristic stages, from simple inflammation to scarring, entropion, and trichiasis. Multiple stages may coexist in various parts of the eyelids. The World Health Organization classifies the stages of trachoma as follows: TF, trachomatous follicular response; TI, diffuse

trachomatous conjunctival inflammation; TS, trachomatous scarring of the palpebral conjunctiva; TT, trachomatous trichiasis; and CO, trachomatous corneal opacification. In the pediatric population, physicians usually encounter only stages TI and TF.[279,302] The scars on the palpebral conjunctiva, referred to as *Arlt lines*, are linear and multidirectional. Slit-lamp examination may reveal a superior limbal corneal micropannus and Herbert pits (i.e., hollowed-out areas at the superior limbus), which represent sites of resolved follicles.

Treatment of trachoma now consists of periodic dosing of susceptible populations with azithromycin or, if azithromycin is not available, topical tetracycline or erythromycin ointment instilled twice daily for 2 months, as well as improved sanitation and hygiene to prevent recurrence.[269] Trachoma can be self-limited if hygiene alone is improved.[268] In children older than 8 years of age, doxycycline should be administered orally daily for 40 days. Erythromycin can be substituted in younger children or in patients intolerant of doxycycline.

Neonatal Conjunctivitis

Neonatal conjunctivitis, or ophthalmia neonatorum, is a common vision-threatening disorder throughout the world, although it has been relegated to a position of secondary importance in the fully industrialized world, where screening and prophylactic measures are widespread. It remains a significant cause of childhood ocular morbidity in poor countries.

Dilute topical silver nitrate solution instilled just after birth for prophylaxis against ophthalmia neonatorum was the first treatment used. In the 1880s it was responsible for reducing the prevalence of gonococcal ophthalmia neonatorum from 10 percent to 0.17 percent of live births in Europe.[269] Silver nitrate has been largely supplanted by other preparations; where it is used, a mild, self-limited chemical conjunctivitis can occur.[199] It lasts 2 to 4 days and resolves with no treatment. Topical erythromycin largely has replaced silver nitrate in developed countries because it is effective without producing a chemical conjunctivitis.[115] In the developing world, dilute povidone iodine solution, 2.5 percent, has proved to be a remarkably effective and inexpensive measure for prevention of *N. gonorrheae* neonatal conjunctivitis when instilled immediately after birth.[132]

In areas of regional conflicts, political instability, and burgeoning refugee populations, even such simple measures are often impossible.[96,115] Causes of neonatal conjunctivitis are highly variable among populations. In areas that use silver nitrate or povidone iodine drops for prophylaxis, chemical conjunctivitis is a common cause of neonatal conjunctivitis.[199] Infectious conjunctivitis occurs in 0.5 to 6.0 percent of live births in the United States. The leading infection is *C. trachomatis*.[18,120,251,269]

Neonatal infection is caused by ocular exposure to contaminated maternal discharge during normal birth, although it may occur in infants born by cesarean section, especially if the membranes rupture prematurely. Other important infectious agents that may cause ophthalmia neonatorum are *N. gonorrhoeae* and *S. aureus*.[95,258] Bacteria that normally reside in the vaginal or gastrointestinal tract occasionally are implicated in ophthalmia neonatorum.

Such bacteria include *Streptococcus* spp., *Haemophilus* spp., *Pseudomonas aeruginosa*, *Moraxella* spp., *Moraxella catarrhalis*, *N. meningitidis*, *E. coli*, and *Enterobacter cloacae*.[241,264] Viruses occasionally produce neonatal conjunctivitis. Rarely, HSV may cause keratoconjunctivitis.[96] It is associated with distinctive vesicular skin changes and systemic signs, and the diagnosis seldom is in doubt.[12]

Life-threatening HSV meningoencephalitis is a serious potential complication of HSV ophthalmia neonatorum.[192] Other viruses occasionally implicated include adenovirus, coxsackievirus A9, cytomegalovirus (CMV), and echovirus.[263]

Certain clinical features may help establish the specific etiologic diagnosis in cases of ophthalmia neonatorum (Table 61-1), but considerable overlap in findings exists, and physicians cannot rely on the history and physical examination alone to make a definitive diagnosis. Even when all appropriate investigative modalities are used, the cause may remain unknown in some cases.

Variations in the time of onset after birth, severity of inflammation, and character of the ocular discharge are common, and none is considered pathognomonic of a specific infectious process, but general considerations are worth reviewing.[241] Silver nitrate chemical conjunctivitis typically begins during the first 48 hours of life and produces a watery discharge with mild inflammation. It is self-limited and resolves within 48 to 72 hours of its appearance.[199] *C. trachomatis* conjunctivitis generally begins 1 to 21 days after birth and usually is apparent by day 7. A moderately copious mucopurulent discharge may be present but can be variable.[120,189] *S. aureus* conjunctivitis also begins during the first 3 weeks of life and can produce a moderately profuse mucopurulent discharge. Many other bacterial agents produce an overlapping clinical picture. Conjunctivitis caused by *N. gonorrhoeae* ordinarily begins somewhat earlier, usually by the third day of life, but it may appear as late as 3 weeks after birth. The hallmark is a copious, hyperpurulent discharge that can reaccumulate in a matter of minutes after it is removed. *N. gonorrhoeae* can penetrate an initially intact cornea and result in perforation of the eye and endophthalmitis.[117,244,263] Conjunctivitis caused by

TABLE 61-1 **Clinical Characteristics of Neonatal Conjunctivitis Caused by Various Agents**

Agent	Day of Life at Onset	Discharge
Silver nitrate	1 (0-2)	Serous
Chlamydia trachomatis	7 (1-21)	Mucopurulent
Staphylococcus aureus	5 (1-21)	Mucopurulent
Neisseria gonorrhoeae	3 (0-21)	Purulent
Other bacteria	7 (1-21)	Mucopurulent
Herpes simplex virus	5 (0-21)	Serosanguineous
Other viruses	Not established	Probably serous

gastrointestinal flora often begins within a few days of birth and can produce a copious purulent discharge.

Viral neonatal conjunctivitis is a rare occurrence. HSV infection may begin during the first 3 weeks of life and usually produces a serous or serosanguineous discharge.[96,192] Other viruses have highly variable characteristics, but a serous discharge is a common finding.

The differential diagnosis of neonatal conjunctivitis includes congenital glaucoma, dacryostenosis with or without dacryocystitis, keratitis, and uveitis. Dacryostenosis is manifested as epiphora and a watery or purulent discharge. Occasionally, conjunctivitis may develop. Because epiphora caused by congenital dacryostenosis ordinarily is not seen until the second or third week of life, it rarely is a serious consideration. Newborns with congenital glaucoma often are photophobic and irritable.[288] They may exhibit increased tearing, conjunctival injection, and corneal edema. Both keratitis and uveitis most often are accompanied by photophobia and pain. The discharge with keratitis can vary but with bacterial causes is purulent. The discharge with uveitis, if present, is watery.

Laboratory testing is important in establishing a specific diagnosis and should include Gram and Giemsa stains, a chlamydial immunoassay, and cultures for aerobic and anaerobic bacteria. Cotton-tipped swabs should be used to obtain material for culture from the conjunctival fornices. Viral and chlamydial cultures and immunoassays can be considered but usually are unnecessary.[17,272] Gonococcal immunoassay and HSV immunochemical tests are available but not in widespread use.

The initial treatment of neonatal conjunctivitis depends on the suspected infectious agent. Broad-spectrum treatment should be considered if the diagnostic possibilities cannot be narrowed. Silver nitrate–induced conjunctivitis is self-limited and does not require treatment. *C. trachomatis* conjunctivitis is treated with tetracycline (1%) or erythromycin (0.5%) ointment four times daily for 3 weeks and with systemic erythromycin for 2 to 3 weeks to prevent or to treat chlamydial pneumonia. Sulfonamides can be used to treat chlamydial conjunctivitis if erythromycin is not tolerated. Topical antibiotics alone are insufficient for the treatment of neonatal *Chlamydia* infection.[106,116,120] Staphylococcal conjunctivitis can be treated with erythromycin ointment or a variety of other topical antimicrobial agents every 4 to 6 hours for 3 to 7 days. Appropriate systemic antibiotic treatment should be considered if the infection is particularly severe.[269]

N. gonorrhoeae infection requires systemic treatment in all cases. Aqueous penicillin G can be considered if resistant strains are unlikely. However, one dose of intramuscular ceftriaxone is the treatment of choice in the United States because it is effective against all *N. gonorrhoeae* strains.[14,225] Eyes should be irrigated with saline every hour until the discharge clears and then in reduced frequency as necessary to reduce the risk for development of corneal infection. This interval usually is 24 to 48 hours after the initiation of systemic treatment.

Penicillin G drops are recommended by some ophthalmologists, but such drops do not appear to improve the overall prognosis or speed of recovery.

HSV neonatal conjunctivitis is treated with systemic acyclovir in appropriate doses for as long as 3 weeks.[96] Treatment should be instituted on an emergency basis because of the potential for development of serious permanent neurologic sequelae and death if treatment is delayed. Topical ophthalmic vidarabine or trifluridine also should be applied to the eyes four times daily for 2 to 3 weeks.

Prevention of ophthalmia neonatorum is simple and requires only instillation of an antibiotic or antiseptic agent within the first hour after birth. Silver nitrate drops (1%), erythromycin ointment (0.5%), and tetracycline ointment (1%) have been effective treatment against *N. gonorrhoeae* and *C. trachomatis*.[116,269] A 5 percent solution of povidone-iodine also has been effective and economical in prophylaxis against a variety of agents, including gonococcal neonatal conjunctivitis. It may be particularly useful in developing countries.[132] As with other sexually transmitted diseases, neonatal conjunctivitis caused by *N. gonorrhoeae*, *C. trachomatis*, or HSV should be addressed according to standard public health policies, with reporting, investigation, and case identification as required by local law.

KERATITIS: CORNEAL INFLAMMATION

The cornea, with its overlying tear film, is the major refracting component of the human eye. Keratitis means inflammation of the cornea. Microbial keratitis means inflammation of the cornea caused by infection with a microorganism.

Any irregularity of the corneal tear film, the surface of the cornea itself, or an opacity of the cornea involving the central visual axis may impair vision. The cornea is composed of five distinct layers: the epithelium, Bowman's layer, the stroma, Descemet's membrane, and the endothelium. The epithelium is several layers thick and, when healthy, can regenerate without scarring after an injury or other insult. The Bowman membrane lies beneath the epithelium. It does not regenerate, and it heals with a scar when injured. The stroma is the thickest part of the cornea. It is composed of regularly arranged collagen fibrils embedded in a matrix of mucoproteins and glycoproteins. Like the Bowman membrane, the stroma heals with scarring.

Descemet's membrane is the basement membrane of the corneal endothelium. It can regenerate after an insult and does not opacify. The innermost layer, the endothelium, is derived from neuroectoderm and consists of a single layer of cells that do not have significant regenerative capacity. The cornea is an avascular structure that is clear because of the regular arrangement of the collagen fibers in the stroma and the dehydrating pumping action of the endothelium. The cornea will become edematous and opacify if the endothelium is significantly damaged or diseased. The external corneal surface is protected from injury and exposure by the eyelids. Reflex tearing in response to mechanical irritation provides further protection. The blink response to threat and the antimicrobial properties of the tear film further protect the cornea from injury and infection.

Patients with keratitis usually have erythema of the perilimbal bulbar conjunctiva (limbal flush) and pain. Additional complaints may include decreased vision and photophobia. The diagnosis of keratitis depends on the presence of a corneal epithelial or stromal infiltrate. The infiltrate is verified by slit-lamp examination and can be extremely difficult to see in infants and uncooperative or frightened children. Ideally, the patient is examined with a slit-lamp; sometimes sedation is required for this. Stains and cultures are usually required to establish the diagnosis, preferably before topical antibiotics are started, so an ophthalmologist should be consulted promptly. Rarely, a biopsy of the cornea is needed to obtain material for culture. Even more rarely, a corneal transplantation is required to stop progression of an infection or to treat a corneal perforation. Exact etiologic diagnosis is based on clinical findings and on examination of stains and cultures.

Isolated Epithelial Keratitis

Keratitis can be classified according to the layer of cornea involved. Most infections involve the epithelium and/or the stroma. Isolated epithelial keratitis usually is caused by one of several viruses: HSV, varicella-zoster virus (VZV), adenovirus, EBV, and the (rubeola) measles virus. The first three organisms have been discussed in an earlier section.

EBV causes HSV-like dendritic corneal epithelial lesions; stromal disease also may occur. The lesions are self-limited and do not respond to antiviral therapy.[172] Measles keratitis usually consists of transient epithelial infiltrates, which resolve without permanent sequelae.[142] In malnourished children with vitamin A deficiency, measles represents a serious threat to life and to vision. Deep corneal ulcers may develop during the first few days of measles infection. Vitamin A deficiency remains the most common cause of pediatric blindness worldwide, almost exclusively involving children in developing countries. Measles is a common comorbidity factor. When a vitamin A–deficient child develops measles and keratitis, rapid progression leading to corneal perforation and ultimate loss of the eye may occur.[24,93] Whether the ulcers are caused by direct measles virus infection, by the keratomalacia (corneal melting) of vitamin A deficiency, or by some combination of these factors is still not entirely clear.

Measles immunization programs plus periodic mega vitamin A dosing programs, for susceptible children under 6 years of age, greatly reduces childhood blindness and childhood mortality in developing countries.

Stromal Keratitis

Syphilis and certain parasitic and viral infections can cause a nonsuppurative keratitis isolated to the corneal stroma. Congenital syphilis produces interstitial (stromal) keratitis in children, although the condition usually does not become apparent until late in the first decade of life. An indolent, peripheral corneal haze develops and slowly progresses centrally. Ghost vessels devoid of blood flow are seen in the corneal stroma on slit-lamp examination.[271] The condition is manifested as a bilateral stromal process[247] in 80 percent of cases and is accompanied by transient iritis, iridocyclitis, or scleritis at some point in the course of the disease. When ocular syphilis is diagnosed, systemic infection is present, by definition. The systemic disease must be treated according to accepted guidelines.

Bacterial Keratitis

Bacterial keratitis, usually involving a corneal ulcer, most often occurs after trauma that disrupts the normal integrity of the corneal epithelium. The trauma can be mild and occult, such as that caused by lens wear. *S. aureus*, *S. pneumoniae*, *P. aeruginosa*, and *Moraxella* spp. are the most common bacterial causes of severe necrotizing bacterial keratitis.[10,158,188,285] Other organisms, such as *S. epidermidis*, *Actinomyces* spp., viridans streptococci, and a variety of others, have been implicated in less severe cases. Accurate identification of the offending organism greatly facilitates effective treatment. A specimen is obtained by scraping the edge of the ulcer with a sterile platinum spatula. Smears should be fixed in 70 percent methanol, not by heat, and Gram stain for bacteria and acridine orange stain for fungi and *Acanthamoeba* are recommended. The yield of culture-positive cases is higher in laboratories skilled in handling corneal cultures. Material for culture should be inoculated onto fresh media such as blood and chocolate agar (aerobes and facultative anaerobes), Sabouraud agar (fungi), and thioglycolate broth (anaerobic bacteria). Thayer-Martin agar should be plated if *N. gonorrhoeae* is suspected. Initial treatment is based on the resulting stains (Table 61-2) and modified pending cultures (Table 61-3).[20,157]

Typically patients are started on frequent fortified tobramycin and ceftazidime drops until culture results become available. Medical treatment of bacterial keratitis includes fourth-generation fluoroquinolones, fortified topical antibiotics, and, occasionally, subconjunctival antibiotic injection (see Table 61-2).[44,202,269] Antibiotics are administered as often as every 15 to 30 minutes initially. Systemic antibiotics are required only for gonococcal, chlamydial, and onchocercal keratitis, as well as for actual or threatened perforation of the cornea, extension of infection to the sclera, or worsening of the process during topical or periocular treatment (or both). Topical steroids are useful if the resulting inflammation threatens to destroy the mechanical or optical integrity of the cornea, but steroids are never used as isolated treatment.[269]

Fungal Keratitis

The most common causes of fungal keratitis include *Candida*, *Aspergillus*, and *Fusarium*. Mycotic keratitis associated with the filamentous fungi *Aspergillus* and *Fusarium* is thought to occur with trauma, whereas keratitis caused by *Candida* is associated more commonly with a preexisting ocular (e.g., dry eye) or systemic (e.g., diabetes mellitus or immunosuppression) condition.[275] Fungal keratitis tends to be relatively indolent in contrast to bacterial keratitis. Typically, white stromal infiltrates

with irregular and indistinct borders are detected. Satellite lesions, separated from the main lesion, may be evident. Mild iritis is common. Severe iritis with hypopyon can occur but is an infrequent manifestation in fungal corneal keratitis.[203] For possible fungal keratitis, an acridine orange stain is recommended and culture on a Sabouraud agar plate is indicated. Hyphal fungi are treated with topical natamycin, topical fluconazole, systemic fluconazole, or some combination of these medications. Yeasts are treated with topical or systemic amphotericin B, fluconazole, or both agents.[94]

Protozoan Keratitis

Protozoan keratitis is a particularly serious vision-threatening process. It usually is caused by *Acanthamoeba*

and occurs more frequently in wearers of soft contact lenses. Use of homemade saline solution is a significant risk factor and should be discouraged.[37] Amoebae are ubiquitous organisms in soil, water, and air. They have been identified in hot tubs and in the feces of domestic animals.[172] People living in rural areas may be at special risk.

Acanthamoeba keratitis has been reported in children without a history of contact lens use or trauma.[62] *Acanthamoeba* corneal ulcers are pleomorphic.[131] Older lesions may exhibit a ringlike infiltrate around a central ulcer. Iritis or iridocyclitis may be intense, and severe pain is a hallmark of the disease. Acridine orange and calcofluor white stains aid in establishing an early diagnosis.[171] Tandem scanning confocal microscopy of corneal specimens may increase diagnostic accuracy, and the organism may grow on blood and chocolate agar.[37,167,216] Treatment of *Acanthamoeba* keratitis is complex and suboptimal. Topical application of polyhexamethylene biguanide (0.02%),[153] chlorhexidine (0.02%), paromomycin (0.1%), or propamidine isethionate (Brolene) drops may be effective. Oral itraconazole (Sporanox) has been used successfully in adults.[150,167,176] Cycloplegic agents are recommended for comfort, and pain medications are often required.

Corneal transplantation is done if the infection progresses despite treatment, if perforation occurs, or if significant corneal visual axis opacification remains after the active infection is eradicated.

Onchocerca volvulus is a filarial parasite that causes river blindness (i.e., onchocerciasis). The disease is endemic in sub-Saharan West Africa, in isolated areas of East and Central Africa, and in some areas of Central and Northern South America. The organism is transmitted by the bite of a blackfly of the family Simuliidae.[235] Larvae migrate to subcutaneous tissue and pass through several molts to become adult worms, which encapsulate in nodules and produce microfilariae that pass into blood, skin, and other organs, including the eyes. The conjunctiva, cornea, aqueous humor, vitreous, retina, uveal tract, sclera, and optic nerve all may be infested. Corneal involvement can lead to vision loss caused by corneal opacification, but most severe vision loss is caused by choroidal, retinal, and optic nerve disease.[114] Although children are often infected, blindness usually does not occur until they reach the third or fourth decade of life.[278,288]

Treatment of onchocercal infection is administration of ivermectin every 6 to 12 months to all individuals living in endemic areas. Ivermectin kills the microfilariae but not the adult worms, which live in subcutaneous nodules and remain until their death.[274] The adult worm may live 10 or more years. Because of the long life span, ivermectin should be taken every 6 months for at least 10 years to treat microfilariae as they develop.

Microsporidia are intracellular protozoa that represent a new emerging ocular pathogen. Interest in the organism has increased in the last decade because of its association with HIV and acquired immunodeficiency syndrome (AIDS). The ocular manifestation corresponds to both the immune status of the patient and the genus of microsporidia involved.[139] Typically, keratoconjunctivitis occurs in immunocompromised individuals and stromal keratitis is seen in immunocompetent individuals. Keratoconjunctivitis is manifested as bilateral conjunctival inflammation and epithelial keratopathy, which may lead to decreased vision. Stromal keratitis is manifested as an insidious diskiform keratitis with uveitis similar to that seen in HSV stromal keratitis and may require penetrating keratoplasty because of perforation or scarring. Potassium hydroxide plus calcofluor white and acid-fast stains are thought to be the most efficient means of establishing the diagnosis of microsporidial keratitis.[140] Transmission electron microscopy provides specificity in identification of the genus and possibly the species, but it may lack sensitivity and is laborious.[139] Knowledge of the genus and species may help guide management. Albendazole, fumagillin, itraconazole, metronidazole, and topical propamidine isethionate have been used as therapeutic agents.[51,139]

INFECTIONS PRIMARILY INVOLVING THE UVEA

The uveal tract is the vascular middle coat of the eye. It is situated between the sclera and the retina. Its major function is to provide nourishment for intraocular tissues, including the retina, lens, and cornea. The uveal tract is composed of the iris, ciliary body, and choroid.

Uveitis is a nonspecific term for inflammation of the uvea. If the inflammatory process primarily affects the iris, it is called *iritis*. If the ciliary body is involved, the process is called *cyclitis*. If these two structures together are involved, the process is called *iridocyclitis* (i.e., anterior uveitis). The term *intermediate uveitis* (i.e., pars planitis) applies to inflammation in the region of the ciliary body and peripheral retina. The term *posterior uveitis* usually applies to combined inflammation of the retina and choroids, also called *chorioretinitis*. If the choroid alone is involved, it is called *choroiditis;* inflammation of the retina alone is called *retinitis.* Because of the thinness and close apposition of these two tissue layers, inflammation in one layer frequently "spills over" into the other. The vitreous body occupies the central area of the eye behind the lens. It is composed of water, mucopolysaccharides, and collagen. Although transparent in a normal, healthy eye, the vitreous is subject to inflammation or vitritis, usually as a result of inflammation in adjacent retinal tissue or in the pars plana.

Causes of uveitis are numerous but can be categorized into two main groups: infectious and noninfectious. Infectious causes are discussed in this chapter. Uveitis in any area of the eye may result in pain, conjunctival or episcleral hyperemia, photophobia, lacrimation, and decreased vision, although these symptoms vary relative to the site and the aggressiveness of the inflammation.

With slit-lamp examination, the hallmark of anterior uveitis is the finding of hazy, proteinaceous aqueous humor, called *flare*, and the presence of leukocytes in the anterior chamber. The cell and flare components are graded independently on a 1+ to 4+ scale. If present in sufficiently great numbers, leukocytes can precipitate in the anterior chamber (with location dependent on gravity)

and form a mass called a *hypopyon*. The cells can aggregate on the back of the cornea and create fine, medium, and large lesions known as *keratic precipitates*. The conjunctiva usually is injected or hyperemic. With chronic inflammation, the border of the pupil often adheres to the anterior surface of the lens. Such adhesions are called *posterior synechiae* and may cause the pupil to have an irregular shape and size, as well as poor reactivity to light. Chronic or recurrent anterior segment inflammation may lead to the formation of a cataract. Iris nodules or atrophy may develop with long-standing inflammation. Anterior vitreous cells may occur as a spillover phenomenon in the setting of a prolonged or vigorous anterior chamber reaction. Although inflammatory effects on the ciliary body generally compromise its production of aqueous humor and thereby reduce intraocular pressure, cellular and proteinaceous debris can occlude aqueous humor outflow channels and lead to elevated intraocular pressure.

Inflammation primarily involving the posterior segment of the eye usually leads to decreased vision, which may be the symptom for which treatment initially is sought. Pain may be minimal or absent. Inflammatory lesions of the retina and choroid also may lead to the development of cellular debris in the vitreous and cause the patient to perceive "floaters." Initially, the borders of the retinal or choroidal inflammatory foci often are indistinct and cream-colored. In the healing phase, the borders of these lesions increasingly become distinct, and a defined, partially pigmented scar results. Inflammatory perivascular sheathing of the retinal vessels may occur, as well. Involvement of the macula with edema or exudates may result from inflammation of the posterior segment, and long-standing edema may evolve into a cystic configuration and cause loss of central visual acuity. The optic nerve may exhibit an inflammatory response; if the optic disk is so involved, the response is called *papillitis*. Inflammatory debris also may be found in the vitreous.[4,206,304]

Under normal circumstances, the amount of immune traffic within the eye, especially in the anterior chamber, is held to a minimum by a group of immunomodulatory pathways that together form anterior chamber–associated immune deviation (ACAID). Chief among these deviations is active suppression of delayed hypersensitivity; distinctive ocular antigen-presenting cells migrate to the spleen, where they generate an immune response deficient in $CD4^+$ cells but high in $CD8^+$ cells. These regulatory T cells return to the eye to suppress the $CD4^+$ populace, thereby minimizing the arm of inflammation most likely to impair visual clarity.[91,264]

Epidemiology

In the United States, most uveitis cases have noninfectious causes. Large samples demonstrate a predominance of anterior rather than posterior uveitis. The most common category of anterior uveitis is idiopathic; the most common infectious cause of anterior uveitis is herpetic keratouveitis (simplex and zoster). Posterior uveitis is caused most frequently by *Toxoplasma gondii*. In developing nations, infectious uveitis plays a larger role. In West Africa, *T. gondii* probably accounts for most cases of intraocular inflammation.[232,233]

Viral Uveitis

Herpes Simplex Virus

Most of the uveal inflammation associated with HSV (typically iridocyclitis) results from the corneal disease. Occasionally, a patient will have iritis as an isolated finding, but most patients with ocular HSV demonstrate conjunctivitis, keratitis, chorioretinitis, or retinal vasculitis.[227] The iritis may require treatment with topical steroids and topical antivirals as prophylaxis against the development of corneal epithelial disease.[284,304]

Varicella-Zoster Virus

Occasionally, varicella infection (i.e., chickenpox) may be associated with a transient iritis that requires no treatment. Although rare, cases of unifocal choroiditis causing visual loss but responsive to acyclovir in children with primary varicella have been reported.[186]

Herpes zoster virus may cause iridocyclitis during the acute stage of the disease; the anterior chamber reaction can persist or recur long after resolution of the cutaneous component of the condition. Herpes zoster always should be considered in the differential diagnosis of chronic unilateral iridocyclitis. Topical steroids are indicated for iritis, with the addition of oral or intravenous acyclovir for severe cases. Segmental iris atrophy is a characteristic sequela of herpes zoster uveitis. Glaucoma, hyphema, retinitis, vasculitis, and extraocular muscle palsy occasionally occur in patients with herpes zoster ophthalmicus. In a profoundly immunosuppressed patient, VZV can cause a devastating retinitis known as *progressive outer retinal necrosis*.[156]

VZV and HSV-2 have been implicated as causes of acute retinal necrosis syndrome. Patients in whom this syndrome is diagnosed range from 13 to 71 years of age, with an average age of 43 years. The syndrome typically occurs in healthy patients. The virus causes a triad of acute vitritis, retinal vasculitis, and peripheral necrotizing retinitis and is bilateral in 33 percent of patients. Treatment consists of intravenous acyclovir. Prophylactic laser photocoagulation may prevent retinal detachment. The visual prognosis is guarded.[26,156]

Epstein-Barr Virus

Ocular EBV involvement has been reported primarily in patients with infectious mononucleosis. Follicular conjunctivitis may be diagnosed in 2 to 40 percent of patients. Corneal stromal inflammation, iritis, episcleritis, optic neuritis, and chorioretinitis occur less commonly. Systemic corticosteroids and acyclovir may be useful in treating sight-threatening complications of chronic intraocular inflammation from EBV infection.[174] Postinfectious uveitis also has been described and is discussed later.

Enteroviruses

Coxsackievirus A24 and enterovirus 70 may cause a painful follicular conjunctivitis called acute hemorrhagic conjunctivitis. Rarely, chorioretinitis may be diagnosed. Treatment of these infections primarily is supportive.[206]

Rubella Virus

Rubella virus can cause congenital and acquired infections. Ocular manifestations of acquired rubella include conjunctivitis in 70 percent of patients, superficial keratitis, and iritis. Rarely, retinitis has been reported.

Congenital rubella syndrome can be manifested as cataracts, glaucoma, microphthalmos, and retinitis. Cataracts occur in 15 percent of patients and glaucoma in 10 percent. Retinal examination reveals a salt-and-pepper fundus caused by the alternating pattern of hypopigmentation and hyperpigmentation of the retinal pigment epithelium. The prognosis for patients with retinitis alone usually is good, with vision between 20/20 and 20/40. Glaucoma resulting from rubella commonly requires surgery, as do the cataracts. Iritis is reported less commonly.[138,174]

Mumps Virus

Ocular manifestations of mumps virus include dacryoadenitis, conjunctivitis, iritis, optic neuritis, and keratitis. Retinitis also has been reported. The prognosis for visual recovery from the retinitis is good, and sequelae of the iritis are rare occurrences.[94,174]

Measles Virus

Measles virus can cause congenital and acquired infections. In congenital infections, a salt-and-pepper retinopathy and cataract formation may occur, similar to that found in rubella. Ocular manifestations in acquired measles include conjunctivitis and, much less commonly, retinitis, retinal vasculitis, and optic nerve edema.[15,206]

Subacute Sclerosing Panencephalitis

Between 30 and 75 percent of patients with subacute sclerosing panencephalitis (SSPE or Dawson inclusion body encephalitis) have ocular findings. SSPE is caused by a variant of the measles virus; it differs from the wild-type virus by alteration or absence of viral M protein. Optic nerve edema, inflammation, and subsequent optic atrophy have been reported. Macular retinitis is a common finding, and the contiguous non-neural tissues (vitreous and choroid) almost never are involved. The visual prognosis of survivors is poor.[201,206]

Creutzfeldt-Jakob Disease

The most common ocular manifestation of Creutzfeldt-Jakob disease is cortical blindness. Optic atrophy may result from degeneration of the neurons of the optic nerve.[206]

Human Immunodeficiency Virus and Acquired Immunodeficiency Syndrome

As many as 75 percent of patients with advanced AIDS have ocular findings. Cotton-wool spots occur in more than 50 percent of patients and are bilateral in more than 80 percent. Cotton-wool patches represent focal infarctions of the neural layer of the retina and are the most common ocular finding in patients with AIDS. They generally produce no symptoms and do not decrease vision. These spots are white and fluffy and occur most commonly in the macular portion of the retina. They resolve in 4 to 6 weeks with no residual scars. Occasionally, flame-shaped hemorrhages are detected as well. The retina and choroid in these patients may become infected with HSV, CMV, VZV, syphilis, tuberculosis, ocular histoplasmosis, *Candida*, toxoplasmosis, and *Pneumocystis*, although in the highly active antiretroviral therapy (HAART) era, the incidence of CMV retinitis has declined and its advance in existing cases has been slowed or halted. Symptomatic anterior uveitis in the absence of the aforementioned pathogens occurs rarely in patients with AIDS and may be caused by HIV itself.[133]

Cytomegalovirus Infection

CMV infections may occur in preterm neonates and immunosuppressed patients, especially those with AIDS. In neonates with symptoms of CMV infection (i.e., low birth weight, microcephaly, jaundice, thrombocytopenia, hepatosplenomegaly, or petechial rash), congenital CMV infection[21] (i.e., prenatal transmission) may be manifested in the fundus as chorioretinal scars (21%) and optic atrophy (7%).[48]

CMV retinitis develops in approximately 30 percent of adult patients with AIDS, usually those with $CD4^+$ counts less than $50/mm^3$.[77] In the pediatric AIDS population, $CD4^+$ counts of less than $20/mm^3$ may be required for appearance of the retinitis.[75] The disease is less common in pediatric patients with AIDS. Patients with CMV retinitis have no external ocular signs but may complain of loss of vision. Children may not complain of such loss, and the problem may become apparent only after bilateral severe vision loss has occurred.[75] The retinal lesions of CMV typically are yellow-white and often are associated with hemorrhage. The retinitis generally follows a perivascular distribution. The retina becomes necrotic and eventually atrophies, with a gliotic scar. CMV optic neuritis also may develop. Treatment consists of intravenous or intravitreal ganciclovir, intravenous or intravitreal cidofovir, or intravenous foscarnet[78,304] and can often be discontinued when the $CD4^+$ count rises above $100/mm^3$.[277]

Parvovirus Infection

Bilateral panuveitis has been reported to be associated with parvovirus B19 infection.[166]

Human T-Cell Lymphotrophic Virus Infection

Human T-cell lymphotrophic virus is endemic in several regions of the globe: Japan, the Caribbean islands, and parts of central Africa. It probably is responsible for several cases of self-limited, occasionally recurrent uveitis in these regions.[193]

Lymphocytic Choriomeningitis Virus Infection

Lymphocytic choriomeningitis virus (LCMV) is an arenavirus endemic in mice; it also is reported in hamsters

and occasionally is transmitted to humans by direct contact with the rodent or through aerosolization of its feces or urine. Postnatal exposure results in asymptomatic seroconversion or aseptic meningitis, but intrauterine infection can have devastating consequences. Spontaneous abortion, congenital hydrocephalus, psychomotor retardation, and chorioretinitis have been documented. Diffuse chorioretinal scarring identified postnatally may bode a grim visual prognosis. LCMV may be an underdiagnosed cause of unexplained congenital chorioretinitis. The diagnosis is confirmed by elevated LCMV antibody titers. A survey of severely retarded, visually disabled children revealed immunologic evidence pointing to LCMV as the cause of the visual loss in approximately half of those surveyed.[179,181]

Viruses

Rift Valley Fever Virus. Rift Valley fever virus is an insect-borne virus. The arthropod vector directly inoculates the virus into the bloodstream of a host, resulting in end organ infections, including the retina. Cattle and sheep are the primary host, and mosquitoes are the vector for transmission. Outbreaks have been reported in eastern and sub-Saharan Africa and South Africa. Uveitis and conjunctivitis can occur in the acute phase of the disease.[67,252] A viral retinitis may occur 1 to 3 weeks after the illness. It may be unilateral or bilateral, affecting both the central and the peripheral fundus with hemorrhages, exudates, and retinal vasculitis.

Herpes B Virus. Herpes B is an α herpes virus within the herpes virinae family. Transmission to humans occurs via bites or scratches from infected monkeys where the virus is endemic. Infection may also occur via puncture wounds from contaminated objects.[194,234]

Herpes B virus has been associated with ocular complications in persons handling monkeys.[194,234] The reports suggest that the virus can cause retinal disease indistinguishable from acute retina necrosis syndrome, with multifocal necrotizing retinitis and panuveitis in an immunocompetent host.

Influenza A Virus. Influenza A virus is a pneumotropic virus with affinity to the branchial epithelial cells. It is transmitted by droplet infection.[23] Ocular manifestations in influenza include conjunctivitis, keratitis, iritis, and dacryoadenitis during the acute phase of the disease. Retinal involvement with influenza A virus has been reported. Retinitis of influenza A is typically bilateral and predominantly affects the macula with hemorrhages, exudates, and macular edema. Fluorescein angiography reveals diffuse vascular leakage. Optic disc edema may rarely be seen. The disease is typically self-limited, with return of vision to 20/20.[223]

Bacterial Uveitis

Syphilis

Syphilis *(Treponema pallidum)* should be considered as a possible cause in all cases of intraocular inflammation. Any patient with confirmed syphilitic uveitis should undergo a lumbar puncture to rule out asymptomatic neurosyphilis.

Ocular manifestations of congenital syphilis include interstitial keratitis, a mottled salt-and-pepper fundus, and chorioretinal scarring. Acute interstitial keratitis occurs as a late manifestation of congenital syphilis (5 to 25 years of age) and is thought to be a hypersensitivity response to treponemal antigen in the cornea. Patients complain of pain and photophobia and have a diffusely opaque cornea and anterior uveitis. Blood vessels invade the inflamed cornea and eventually are obliterated, with ghost vessels left in the corneal stroma. Glaucoma may occur. A unilateral manifestation of interstitial keratitis suggests postnatally acquired lues.

Secondary syphilis may involve any layer of the eye. Episcleritis, scleritis, iridocyclitis (acute, chronic, or recurrent), iris capillary dilation (i.e., iris roseata), vascular papules of the iris (i.e., iris papulosa), inflammatory nodules (i.e., iris nodosa), choroiditis, chorioretinitis, and retinal vasculitis all have been reported, as have optic neuritis and subsequent atrophy.

Tertiary syphilis may have associated gummata of the iris and an Argyll Robertson pupil (i.e., miotic, irregularly shaped pupil with loss of response to light but preservation of the near response). Intraocular inflammation seldom occurs at this stage.

Ocular inflammation secondary to syphilis should be treated as neurosyphilis. With the appropriate doses of penicillin G, the inflammation typically resolves rapidly. Occasionally, topical regional steroids are required to control local inflammation. Treatment of ocular syphilis may lead, at least initially, to a vigorous local and systemic self-limited, febrile response, presumably caused by liberation of spirochetal antigens or toxins. Topical oral corticosteroids may be required to quell this response, which is also known as a *Jarisch-Herxheimer reaction*.[4,170,206]

Lyme Disease

A mild follicular conjunctivitis occurs in 11 percent of patients with stage 1 Lyme disease, caused by *Borrelia burgdorferi*. During the second and third stages, neuro-ophthalmic manifestations, including cranial neuropathy (most often cranial nerves III, IV, VI, and VII), optic neuritis, bilateral keratitis, bilateral iridocyclitis, diffuse choroiditis, vasculitis, intermediate uveitis, and Parinaud oculoglandular syndrome, may be seen. The most frequent manifestation of late Lyme disease is arthritis. Ocular inflammation occurs in approximately 4 percent of children with Lyme arthritis.[130] Early, localized Lyme disease may be treated with doxycycline (8 years of age and older) or amoxicillin. More advanced or persistent disease is treated best with intravenous ceftriaxone.[6] Antibiotic treatment early in the course of the disease carries a better prognosis than does therapy initiated at later stages.[22]

Leptospirosis

Leptospirosis may cause an anterior uveitis that occurs months after the acute infection. Leptospirosis is identified as an important cause of epidemic panuveitis in

southern India; the most common posterior segment manifestations in this group are vasculitis and vitritis.[46]

Tuberculosis

Any structure of the eye may be affected by tuberculosis. Allergic and infectious processes have been implicated as important causes of tuberculous uveitis. Anterior uveitis with or without keratitis has been attributed to tuberculosis. Choroiditis, optic neuritis, and orbital infections have been detected in cases of miliary tuberculosis. The most frequent manifestations of ocular tuberculosis are choroidal nodules and scars; anterior uveitis is an uncommon occurrence.[30] Treatment should be undertaken with the appropriate antituberculous medications. Corticosteroids often are necessary in conjunction with antimicrobial therapy.

Leprosy

Because *Mycobacterium leprae*, the cause of leprosy, grows best at lower temperatures, corneal infections predominate. Corneal involvement is associated with prominence of the corneal nerves, interstitial keratitis, and corneal hypoesthesia, but corneal opacities are often peripheral and not visually significant.[56] Uveal involvement in leprosy frequently is silent and accounts for a large number of the ocular complications from the disease.[56,57]

Brucella *Infection*

Ocular manifestations of *Brucella* infection are rare but include iritis, focal nodular choroiditis, and panophthalmitis.[206]

Cat-Scratch Disease

Bartonella henselae is a gram-negative rod transmitted to humans by the bite or scratch of an infected animal, often a young cat or kitten. Regional lymphadenopathy is the predominant nonocular finding. A striking stellate neuroretinitis characterized by swelling of the optic nerves and lipid deposition in the retina is the most easily identifiable complication of ocular infection. Other manifestations include intermediate uveitis, optic disk swelling, multifocal choroiditis, and serous macular detachment. The discrete foci of multifocal choroiditis are the most common findings in the posterior segment. The role of antibiotics in this condition is debated.[146,259]

Fungal Uveitis

Histoplasmosis

The diagnosis of presumed ocular histoplasmosis syndrome is based on the clinical picture of disseminated punched-out retinal "histo spots," atrophic retinal changes around the optic nerve, and a clear vitreous.[220] Later in the course of the disease, subretinal hemorrhage and retinal detachment may occur. Ocular histoplasmosis often is bilateral and can result in legal blindness from the loss of macular vision. Presumed ocular histoplasmosis syndrome may occur after an episode of benign systemic histoplasmosis during childhood. Active inflammation and vitreous cells usually are not seen in this syndrome, although case series have documented active chorioretinal inflammation as new-onset lesions and as reactivation of previously quiescent lesions.[42,141] The hallmark histoplasmosis spots appear as white, punched-out, well-demarcated chorioretinal scars and represent healed fungal lesions. Generally, they first appear during adolescence, do not reduce vision, and do not require treatment. Macular disease, which may reduce vision, does not develop until after the patient reaches the second decade of life. Subretinal neovascularization may develop at the site of a macular histoplasmosis spot, with fluid, blood, and lipid accumulating in the subretinal space. This process plus local scarring can result in a marked reduction in central vision.

Macular neovascularization may be treated suitably with laser photocoagulation in an attempt to salvage the remaining central vision. Antifungal drugs may play a role in the unusual setting of demonstrated active histoplasmosis choroiditis.[240]

Candidiasis

Candida spp., including *Candida albicans*, are fungi with yeast and filamentous forms. Candidiasis is encountered in immunocompromised patients and in situations involving indwelling catheters, intravenous therapy, chronic antibiotic use, poorly controlled diabetes, and intravenous drug abuse. Candidal chorioretinitis can develop in approximately 9 percent of patients with blood cultures positive for the fungus,[75] although more recent studies have demonstrated that ocular involvement (either chorioretinitis or endophthalmitis) in children is a rare occurrence.[74]

In the eye, *Candida* infection usually begins in the choroid and eventually causes multifocal white chorioretinal lesions. If the fungus proliferates unchecked, it may break through the retina into the vitreous and produce the classic white snowball-like "fungus ball." Candidal infection that progresses to endophthalmitis is exceedingly rare if appropriate intravenous antifungals are started promptly on notice of a positive blood culture.

Intravenous amphotericin B is the drug of choice. Other antifungal agents such as fluconazole, flucytosine, and miconazole also may be effective, but none is dramatically so. Surgical treatment of intraocular *Candida* disease is discussed in the section on endophthalmitis.

Aspergillosis

Aspergillus spp. can infect the choroid, retina, and vitreous of immunocompromised individuals. One group of investigators found a high rate (7%) of these unusual infections on reviewing records of deceased liver transplant recipients.[129]

Coccidioidomycosis

Coccidioides spp. have yeast and filamentous forms. Ocular disease consists of a multifocal chorioretinitis that

develops during the course of systemic coccidioidomycosis. The lesions initially appear similar to those seen in histoplasmosis; in severe cases, endophthalmitis results, and vitrectomy may need to be performed. In less severe cases, the lesions may respond to intravenous amphotericin B. Occasionally, an isolated granulomatous iridocyclitis may develop.[187]

Cryptococcosis

Cryptococcus neoformans is a yeastlike fungus that can cause multifocal chorioretinitis and endophthalmitis. Most patients with cryptococcosis are severely immunocompromised, and many have AIDS. The CNS and eye are involved commonly, and elevated intracranial pressure may cause papilledema and sixth cranial nerve palsy. Intravenous amphotericin B in combination with oral flucytosine is the treatment regimen of choice.[6,147]

Sporotrichosis

The dimorphic fungus *Sporothrix schenckii* is encountered commonly in rotting vegetable matter, wood, and soil. The fungus gains access to the host by traumatic implantation or inhalation. It has been reported to be responsible for anterior uveitis in the setting of a suggestive lesion on a finger of the dominant hand, with presumed hand-to-eye transmission.[287]

Protozoal Uveitis

Leishmaniasis

Ocular leishmaniasis has been described. Manifestations include conjunctivitis, blepharitis, and anterior uveitis. This trio of findings responds to systemic treatment with sodium stibogluconate.[85]

Protozoal Infection

Amebiasis. Humans can be infected by ingestion of the cyst form of *Entamoeba histolytica* in contaminated water and food. The primary disease manifestation in *E. histolytica* infection is dysentery. Ocular involvement is rare and includes maculopathy in the form of a transparent cyst involving the central retina with surrounding retinal hemorrhages and anterior uveitis.[31,148]

Trypanosomiasis. Trypanosomiasis is a flagellated protozoa transmitted by tsetse flies. African trypanosomiasis is caused by *Trypanosoma brucei* and *Trypanosoma cruzi.* General manifestations include headache, general malaise related to fever, lymphadenopathy, and then CNS involvement with sleepiness, coma, and death. Reported ocular manifestations include urticarial swelling of the eyelids, interstitial keratitis, and, rarely, iritis or choroiditis.[231] In American trypanosomiasis, known as *Chagas disease*, intraocular disease has not been reported but eye involvement may occur in the form of eyelid swelling and periorbital edema spreading to the face.

Malaria. The most serious form of malaria is caused by *Plasmodium falciparum*. Hemolytic anemia and disseminated intravascular coagulation are presumed to lead to hypoxia of the brain and other tissues, resulting in the clinical manifestations of the disease. Ocular manifestations include subconjunctival hemorrhage, retinal hemorrhages, and cranial nerve palsies. Corneal involvement and uveitis are not caused directly by malaria.[148,161-163]

Giardiasis. Giardiasis is caused by *Giardia lamblia*, which can inhabit the human jejunum. Humans are infected through ingestion of water contaminated with human sewage. Reported ocular manifestations include retinal arteritis (vasculitis) and salt-and-pepper retinal pigmentary changes.[50,169]

Helminthic Uveitis

Toxocariasis

Toxocara canis causes visceral larva migrans, which is not associated with ocular disease. In the retina, larvae get trapped in small capillaries and burrow into surrounding tissue; the dead larvae incite an intense eosinophilic abscess. Ocular toxocariasis has three classic clinical manifestations, almost always involving one eye only. One form occurs in children 2 to 9 years of age and causes an indolent endophthalmitis and leukokoria (i.e., white pupil). Tractional retinal detachment may occur. The eye typically shows little or no external evidence of inflammation, and the patient experiences no pain.

A second form appears in children between 4 and 14 years of age. These patients have reduced vision but little or no external inflammation and no pain. The reduced vision may cause strabismus, which may be the first sign. An inflammatory granuloma is seen in the macula.

The third form of ocular toxocariasis occurs in patients between 6 and 40 years of age but may not be recognized until years later. Patients with this form of toxocariasis have good vision, but a peripheral retinal granuloma is seen on routine eye examination. Vision may be affected if a traction band from the granuloma distorts the macula.

Inactive *Toxocara* granulomas do not respond to medication. When active intraocular inflammation exists in such a magnitude that it poses a further threat to vision, administration of periocular or systemic steroids may be necessary. Anthelmintic agents eradicate migrating larvae, but their effect on "residing" larvae is questionable. When giving anthelmintics, one should combine them with a short course of corticosteroids because death of the larvae may incite vigorous inflammation. Cryotherapy and laser therapy may be useful when the *Toxocara* granuloma is located away from the macula and optic nerve. Vitrectomy may be helpful if significant traction on the retina occurs. Anthelmintic drugs should not be administered after the patient has undergone posterior segment surgery. Visual prognosis is poor if the macula is involved.[206,242,251,297]

Onchocerciasis

Onchocerciasis often causes a severe choroiditis with an overlying retinitis.[249] The various ocular manifestations of infestation with *O. volvulus* are discussed in the section on keratitis.

Loiasis

The *Loa loa* worm can migrate through the tissues of the eye and cause conjunctivitis, iridocyclitis, vitritis, and chorioretinitis. The disease is transmitted by the bite of a mango fly.[81] Vascular obstruction with intraretinal hemorrhage and retinal exudation may occur as well. Medical treatment with diethylcarbamazine can kill the adult worms and microfilariae. Adult worms also can be removed from the eye surgically.[206]

Cysticercosis

The tapeworm *Taenia solium* causes cysticercosis. When the larva gains access to the eye, cysts form in the vitreous or subretinal space in 13 to 46 percent of patients. The living worm may be seen undulating in these spaces. With death of the organism, severe panuveitis can occur. Orbital and subconjunctival involvement occur less commonly. Surgical removal of the intraocular cysts may prevent the severe inflammation that occurs on death of the worm. Praziquantel can kill the organism, but the ensuing increase in inflammation may be dramatic.[206]

Rare Causes of Parasitic Posterior Uveitis In Children

Schistosomiasis. Schistosomiasis is caused by platyhelminth, which belongs to the trematode class and has three recognized species: *Schistosoma haematobium*, *Shistosoma mansoni*, and *Shistosoma japonicum*. Humans are infected when the larval form (cercaria) emerges from its snail and pierces the skin to enter the dermal lymphatics and capillaries. Reported ocular lesions include generalized cutaneous edema of the eyelids in the acute phase, dacryoadenitis, choroiditis, and, rarely, retinal pigment epithelium changes.[71,134,218]

Hydatid disease. Hydatid disease is caused by *Ecchinococcus granulosus*, for which dogs are the primary host.[298] Reported ocular lesions include painless proptosis, subretinal cysts, and, rarely, involvement of the choroid and the vitreous.[105,298]

Coenurus infection is caused by *Multiceps multiceps*, which is a taenoid cystode responsible for coenurus infection. It is a parasite of dogs and related species with sheep acting as an intermediate host. Humans may occasionally become infected. Reported ocular lesions include conjunctival cysts, intraocular cysts, and subretinal involvement. Panophthalmitis and orbital involvement have been reported.[168,299]

Ascaris lumbricoides is a species of *Ascaris* found in humans. Humans are infected by ingestion of water contaminated with eggs containing infective larvae. Ocular lesions, which are rare, include iridocyclitis and chorioretinitis.[136]

Baylisascaris procyonis may cause ocular disease in humans. They are nematodes of the Ascaridida order and humans are infected by ingestion of material contaminated with ova.[280] *B. procyonis* is a presumptive cause of diffuse unilateral subacute neuroretinitis characterized by unilateral vitritis, papillitis, and recurrent grayish lesions affecting the outer retina and the retinal pigment epithelium.

Gnathostoma spinigerum. *Gnathostoma spinigerum* is a spiruroid nematode endemic in East Asia. The human is an accidental host, and infection occurs by eating infected food. Reported ocular lesions include eyelid swelling, orbital cellulites, uveitis, intraocular hemorrhage, central retinal artery occlusion, and tractional retinal detachment.[150,281]

Wuchereria bancrofti. *Wuchereria bancrofti* is prevalent in many tropical areas of the world. Larvae are ingested by suitable species of mosquito feeding on the skin. The larvae undergo further stages of development and become capable of infecting other individuals when they are disgorged in the saliva of the feeding insect. Reported ocular lesions include conjunctival edema, granulomatous iridocyclitis, and subretinal inflammatory lesions.[195]

Trichinosis is caused by *Trichinella spiralis*, which is a nematode parasite of carnivorous animals of widespread distribution. Human infection results from ingestion of infected undercooked pork or game. Reported ocular lesions include painful limitation of the eye movements associated with proptosis and chemosis, edema of the eyelids and the conjunctiva, and, rarely, retinal hemorrhages or papilloedema.[208,270]

Rickettsial disease. *Rickettsia* are obligate intracellular parasites, possessing both RNA and DNA. Unlike viral infections, they respond to antibiotics. They are transmitted by a vector such as ticks, mites, and fleas. The organisms causing the diseases in the following section have been rarely reported as causing posterior uveitis in humans.[80]

Typhus. Murine typhus is recognized in scattered pockets worldwide. It is caused by *Rickettsia mooseri* and is transmitted by the rat louse. Ocular manifestations include chorioretinitis, conjunctivitis, and uveitis.

Spotted Fever. Boutonneuse fever is recognized in the Mediterranean areas, Caspian and Black sea coastal regions, Africa, Southeast Asia, United States, Russia, and Korea. It is caused by *Rickettsia conorii* and is transmitted by ticks. Ocular manifestations include chorioretinitis, conjunctivitis, and iridocyclitis.

Q Fever. Q fever is caused by *Coxiella burnetii*, which is distributed worldwide and is transmitted by ticks. Ocular manifestations include conjunctivitis, episcleritis, uveitis, and chorioretinitis.

Trench Fever. Trench fever is caused by *Rochalimaea quintana* and is transmitted by the human body louse. Ocular manifestations include retinitis and conjunctivitis.

Uveitis Caused by Insect-Induced Disease

Ophthalmomyiasis is the ocular disorder caused by infestation with fly larvae, most commonly the larval form of the sheep botfly *Oestrus ovis*. Maggots may be seen in the conjunctival fornix (cul-de-sac) or inside the eye. Internal ophthalmomyiasis can be diagnosed by noting a motile larva in the anterior chamber, vitreous, or subretinal space. The maggot may leave trails ("railroad tracks") throughout the retina. A mild inflammatory response in the anterior chamber (e.g., iritis and iridocyclitis) or vitreous may occur. Treatment is surgical removal of the larva. Corticosteroids may be used to treat the accompanying intraocular inflammation.[82,206]

Postinfectious Uveitis

Increasingly, attention is being given to the role of bacterial and viral systemic illness in the eventual development of sterile intraocular inflammation. This type of uveitis is thought to be caused by an autoimmune response that occurs between sensitized lymphocytes and host tissues that bear some antigenic similarity to the recently cleared pathogen. Disruption of the ACAID is probably a prerequisite for the development of these postinfectious syndromes. Several reports exist of nongranulomatous anterior uveitis occurring weeks or months after streptococcal infection. These uveitides may be associated with other poststreptococcal findings (e.g., arthritis and glomerulonephritis) or may be the sole manifestation. Treatment with cycloplegics and topical corticosteroids is sufficient for the ocular manifestations.[19,282,301]

Uveitis, predominantly of the anterior type, has been reported to occur after illnesses caused by gram-negative enteric bacteria such as *Klebsiella*, *Salmonella*, and *Yersinia*. These gram-negative–induced uveitides are much more likely to occur in the setting of human leukocyte antigen (HLA)-B27 positivity. The ocular findings often parallel the development of arthritis, thus suggesting that parallel immunologic processes are occurring in both these mesenchymal cavities (i.e., the joint space and the anterior chamber). An association between recent EBV infection and acute tubulointerstitial nephritis and anterior uveitis has been described, with onset of the renal and ocular inflammation occurring several months after the characteristic acute EBV infection.[109]

INFECTIONS INVOLVING PRIMARILY THE RETINA

Eye Manifestations of Intrauterine Infections (TORCHS Complex)

The TORCHS complex is a group of congenital and perinatal infections that may cause severe systemic and ophthalmic abnormalities. The effect of infection with one of the TORCHS organisms—*T. gondii*, others (LCMV, EBV), rubella virus, CMV, herpesvirus, and syphilis—may be evident at birth or manifest later in childhood or adulthood. Congenital EBV infection (i.e., infectious mononucleosis) has been reported to be associated, possibly, with congenital cataracts.[103] All of these infections commonly cause either mild or no clinically evident disease in the mother.[180] The diagnosis cannot always be established on clinical grounds alone, and neonatal and maternal serologic tests must be performed to confirm the clinical suspicion.

Toxoplasmosis

T. gondii is an obligate intracellular parasite that has an affinity for the CNS and retina. The parasite has three forms: tachyzoite, bradyzoite, and sporozoite or oocyst. Human infection may be congenital or acquired. Acquired infection results from the ingestion of undercooked meat contaminated with oocysts or from exposure to the feces of an infected cat, the definitive host. The oocysts release tachyzoites, which multiply intracellularly and result in cell death. In adults, primary acquired infection usually is asymptomatic. The immune response then transforms the tachyzoite into a bradyzoite, which encysts and remains dormant in tissues for years. These cysts have the propensity to rupture sometime later and cause an inflammatory response resulting in recurrent infection.

Congenital infection is transmitted through the transplacental route. In the United States, the reported incidence of congenital toxoplasmosis is 1 case/1000 to 10,000 births.[12,55] Seventy percent of the obstetric population is negative for antibodies and therefore at risk for infection and transplacental transmission to the fetus.[180] Congenital infection is most severe when acquired in the first trimester and can result in chorioretinitis, intracranial calcifications, microcephaly, mental retardation, and deafness.[55,88,90] Symptomatic neonates with disseminated disease have hepatosplenomegaly, lymphadenopathy, jaundice, fever, anemia, pneumonitis, and a poor prognosis. Other ocular manifestations include cataracts, strabismus, microcornea, vitritis, retinal detachment, optic atrophy, microphthalmos, nystagmus, and ptosis.[180] In a prospective study, 15 percent of infected newborns had chorioretinal scars, indicative of infection in utero; 4 percent had active chorioretinitis; and, in 10 percent, retinal lesions developed by the time the children were 1 to 2 years of age. Long-term follow-up studies found that chorioretinal lesions develop in 82 to 85 percent of children with subclinical *Toxoplasma* infection, some with severe visual loss. Infants with asymptomatic toxoplasmosis should undergo regular ophthalmologic examination because retinal involvement can occur later in childhood and adulthood.[32,90,151] Some researchers suggest that all neonates with toxoplasmosis should receive drug therapy, even if they are asymptomatic.[90]

Toxoplasmosis is the leading cause of acquired necrotizing retinitis and, in many cases, represents reactivation of congenitally acquired infection. Clinically, an area of active retinochoroiditis is adjacent to the border of a chorioretinal scar.[90,228] Associated choroiditis and vitritis may be present. Primary acquired ocular toxoplasmosis manifested as retinochoroiditis is well documented also, and reports suggest that this route of infection may be more common than originally thought.[32,126] Recurrent

ocular disease with postnatally acquired toxoplasmosis has been reported.[29]

T. gondii causes a focal necrotizing retinitis with secondary choroiditis and vitritis. Patients may have floaters, blurred vision, and photophobia. Those with macular involvement can suffer significant visual loss. After the inflammation has resolved, a flat, pigmented chorioretinal scar develops. Visual loss depends on the location of the retinal lesion, with peripheral lesions resulting in little or no visual disturbance and macular lesions capable of producing profound visual loss.

Toxoplasma retinochoroiditis is an emerging problem in patients with AIDS and may be the initial manifestation of this syndrome.[293] The clinical appearance often is atypical.[256] Chronic suppressive therapy is necessary because infection recurs with discontinuation of treatment. A combination of pyrimethamine and clindamycin has been reported to be most effective as prophylaxis.[293]

The diagnosis of *Toxoplasma* retinochoroiditis usually is presumptive and is based on clinical appearance and serologic testing. Several serologic tests are available. The standard serologic diagnosis is based on the presence of anti-*Toxoplasma* IgM in any sample or demonstration of a significant rise in antibody titer in paired sera taken 4 to 6 weeks apart. However, in reactivated congenital infections, which many cases are, *Toxoplasma* IgM results are not positive. The antibody tests most commonly used are indirect immunofluorescent assay (IFA) and enzyme-linked immunosorbent assay for IgM and IgA.[103] False-positive results can occur with both tests in the presence of rheumatoid factor. If clinical infection is suspected and the initial testing results are negative, repeat testing or an alternative testing technique should be considered.

Standard treatment of *Toxoplasma* retinochoroiditis is triple therapy with sulfadiazine 100 to 200 mg/kg/day in four divided doses (maximum, 1.5 g), pyrimethamine 2 mg/kg/day for 3 days, then 1 mg/kg/day (maximum, 25 mg/day), and leucovorin (folinic acid) 10 to 25 mg given orally daily for 6 weeks. Folinic acid prevents the leukopenia and thrombocytopenia that may result from pyrimethamine therapy. Weekly complete blood counts and platelet counts are required to monitor toxicity from therapy. Alternative therapy with clindamycin 40 mg/kg/day in four divided doses (maximum, 2.4 g for 6 weeks) rather than sulfadiazine also has been effective.[273] This therapy is less toxic than triple therapy and therefore is better tolerated. In patients with severe intraocular inflammation, systemic corticosteroids can be used with concurrent antimicrobial therapy.

Preventive measures are twofold; first, avoidance of raw meat and cat feces during pregnancy, especially during the first trimester, and second, treatment of a mother known to have contracted the disease during pregnancy with spiramycin, because it has no known teratogenic effects.[53,65,66] In utero pyrimethamine and sulfadiazine treatment of a fetus known to be infected may be effective.[53,55,123]

Lymphocytic Choriomeningitis Infection

LCMV, an arenavirus discovered in 1933, was recognized as a cause of intrauterine infection in 1955 (also see the earlier section on viral uveitis).[182] The common house mouse *Mus musculus* is the natural host and reservoir of the virus, but laboratory mice and pet hamsters also may be infected.[8,122] LCMV may be transmitted to humans by airborne means, rodent bites, or food contaminated by rodent urine, feces, or saliva; the fetus may be infected by transplacental transmission.[103] The diagnosis may be confirmed by LCMV titers.

Systemic manifestations, often devastating, include hydrocephaly, microcephaly, periventricular calcifications, neonatal meningitis, hepatosplenomegaly, cerebral palsy, mental retardation, and seizures.[103] Ocular findings include chorioretinitis, optic atrophy, nystagmus, microphthalmos, strabismus, and cataracts.[182] The chorioretinitis may mimic congenital toxoplasmosis.[33] The most common ocular findings are peripheral chorioretinal scars, although macular involvement is a common occurrence as well. At present there is no effective treatment. Prevention involves avoidance of mice and hamsters by pregnant women.[103,182]

Rubella Infection

The rubella virion is an RNA virus of the family *Togaviridae* that causes a febrile exanthem. Before the advent of rubella vaccine in 1969, rubella, or German measles, epidemics occurred every 6 to 9 years. The last major outbreak in the United States took place in 1964.[14] With preschool immunization programs, most primary cases now reported occur in individuals between 15 and 24 years of age. Transmission occurs by inhalation of aerosolized droplets in the nasopharynx. Primary infection in adults results in a mild febrile illness associated with lymphadenopathy and a rash. The proportion of susceptible nonimmunized women of child-bearing age ranges from 10 to 25 percent. Fetal infection occurs transplacentally, and the likelihood of transmission from mother to fetus is highest (90%) in the first trimester; transmission at this stage can produce severe fetal damage and result in spontaneous abortion, stillbirth, or multiple congenital anomalies.

The classic congenital rubella syndrome, first described by Sir Norman McAlister in Australia in 1949,[182] is characterized by cardiac defects, ocular abnormalities, and hearing deficits. The incidence of ocular and cardiac defects is higher with exposure early in the first trimester; hearing deficits appear to be associated with exposure late in the first trimester. Givens and associates[102] reported that 88 percent had multiorgan involvement. Hearing loss is the most frequent nonocular manifestation.[182] The most common cardiac defects are patent ductus arteriosus, pulmonary artery stenosis, and pulmonary valve stenosis. Other features include microcephaly, thrombocytopenia, hepatosplenomegaly, and mental retardation.

Ocular involvement occurs in approximately 50 percent of infected infants.[99] Pigmentary retinopathy (i.e., salt-and-pepper retinopathy) affects 22 percent of infected infants. The retina has a mottled appearance, most frequently observed in the posterior pole; the optic nerve and vessels usually are normal unless the patient also has glaucoma.

Nuclear cataracts, which affect between 15 and 27 percent of patients, are the second most frequent ocular complication. Glaucoma is seen in approximately 10 percent of eyes; the combination of cataracts and glaucoma is an uncommon finding.[290] Microphthalmos (which occurs in 10 to 63 percent of affected individuals), iris atrophy, and iritis also have been reported.[27] Live virus may persist for years in the lens, so appropriate precautions must be taken during cataract surgery to prevent transmission.[103]

The retinopathy associated with rubella usually is asymptomatic and does not necessitate treatment. In some cases, it can be complicated by subretinal neovascularization, which may require laser or macular surgery. Cataracts cause most visual morbidity. Visual rehabilitation depends on early cataract extraction to prevent deprivation amblyopia, correction of aphakia with spectacles or contact lenses, and careful follow-up. Glaucoma in infants and children can be temporized with topical medications, but most cases require glaucoma surgery.

Congenital rubella has long-term consequences for all organs involved. In nearly two thirds of infants with no manifestations at birth, hearing loss or psychomotor deficits subsequently develop. From an ophthalmic standpoint, individuals with congenital rubella need continued follow-up.[102]

Cytomegalovirus Infection

CMV is an enveloped DNA virus of the family *Herpesviridae*. An estimated 80 percent of adults are infected by the time they reach 40 years of age.[260] In immunocompetent adults, infection is asymptomatic or can cause a mononucleosis syndrome. Individuals can shed virus in saliva, urine, and other body fluids for months to years after initial infection. Transmission occurs through exposure to body fluids, sexual contact, blood transfusion, or organ transplantation, or it can occur transplacentally. Primary infection acquired in the birth canal is not likely to result in serious disease.

Congenital CMV is the most common congenital infection in humans[261] and can result from exposure to the virus in utero or in the birth canal. In utero infection produces more serious disease. CMV infection occurs in 1 percent of all live births, and only 5 to 10 percent of infants with congenital CMV infection are symptomatic. Maternal infection may be primary or recurrent, but primary infection carries the greatest risk (30% to 40%) for transmission of symptomatic CMV disease to the newborn.[260] Blood transfusions from CMV antibody–positive donors also can result in severe CMV infection in the newborn. Systemic manifestations include intrauterine growth restriction (IUGR), thrombocytopenic purpura, microcephaly with periventricular calcifications, hepatosplenomegaly, pneumonia, and sensorineural deafness.[63] In symptomatic congenital CMV infection, the retina is the primary site of ocular involvement. Cytomegalic inclusion bodies are seen in all layers of the retina. Patchy white areas of necrotic retina with hemorrhage and vascular sheathing are seen in the peripheral portion of the retina, although the posterior pole can be affected as well.[160] Nonhemorrhagic retinitis also may be seen, and most affected infants do not have active retinitis at birth, although scars may be visible as evidence of previous disease.[48] Resolution of the retinitis results in an atrophic scar with areas of hyperpigmentation. If retinitis involves the retinal periphery, vision may be normal. However, visual loss may occur if the posterior pole is involved or if optic atrophy or retinal detachment occurs. CMV retinopathy develops in 5 to 30 percent of infants with clinically apparent disease.[83] Microphthalmos, optic nerve hypoplasia, optic atrophy, optic nerve colobomata, anophthalmia, corneal opacities, and anterior segment dysgenesis also have been associated with congenital CMV infection.[125] In addition, cyclopia and anophthalmia have been reported.[160]

The diagnosis of CMV retinitis is based on the clinical appearance and the constellation of systemic symptoms and signs. Recovery of the virus from urine, maternal cervical secretions, saliva, or aqueous humor can confirm the diagnosis. Complement fixation can identify IgM antibodies to CMV that do not cross react with other herpes viruses. Immunofluorescence techniques are more sensitive but less specific than complement fixation.[160]

Treatment of neonatal or pediatric CMV retinitis is based on the results of treatment of adults with CMV retinitis. Ganciclovir has been shown to stabilize and prevent spread of the disease in infants. Maintenance therapy is not required, but continued follow-up is necessary to detect recurrence. Granulocytopenia and thrombocytopenia can result. Retinal detachment requires vitrectomy, membrane peel, and silicone oil to tamponade the detached retina.[39,124]

Herpes Simplex Virus Infection

HSV is a double-stranded, enveloped DNA virus. Both subtypes, HSV-1 and HSV-2, can cause a vesicular skin eruption. HSV-1 typically is isolated from oral-facial infections; HSV-2 usually is isolated from genital infections. After primary infection occurs, HSV can maintain latency in neuronal ganglion cells and reactivate. Transmission occurs by exposure to infected body fluids such as saliva, and the risk for transmission is higher when the individual is symptomatic.[192]

Maternal-fetal transmission occurs through infected genital secretions in the birth canal (HSV-2) or exposure to infected individuals with oral-facial herpetic disease (HSV-1) in the postnatal period. In mothers with active genital disease, the risk for transmission to the neonate is 50 percent with vaginal delivery. Most series report that between 70 and 80 percent of neonatal HSV infection is caused by HSV-2. Neonatal HSV infection is life-threatening, and the mortality rate without treatment is 80 percent.[295] The diagnosis is suspected by the clinical findings—lethargy, respiratory distress, anorexia, vomiting, cyanosis, low birth weight, IUGR, microcephaly, seizures, intracranial calcifications, pneumonia, hepatosplenomegaly, and skin vesicles. The virus may be isolated from skin vesicles or from nasal or conjunctival secretions, CSF, or blood. The mortality rate of untreated neonatal HSV is 49 percent.[103]

Ocular sequelae develop in fewer than 1 percent of immunocompetent adults with HSV infection. In

contrast, 17 to 40 percent of infected neonates have ocular disease.[173,260] Thirteen percent of neonates with HSV have eye involvement. Ocular involvement can range from mild conjunctivitis to severe bilateral necrotizing retinitis and may be unilateral or bilateral. Conjunctivitis is the most common manifestation. Conjunctivitis, keratitis, and, occasionally, retinitis develop 2 to 14 days after birth. HSV retinitis causes punctate, white-yellow lesions in the periphery and the posterior pole accompanied by choroiditis, vascular sheathing, hemorrhage, and vitritis. Chorioretinal atrophic scars with variable amounts of pigmentation around the border result after resolution of acute infection.[127,224] Visual prognosis depends on the severity of disease, macular scarring, optic atrophy, or CNS involvement of the visual pathways. Severe chorioretinitis and cortical blindness are the usual sequelae of HSV infection acquired through transplantation, a rare mode of transmission.

El Azazi and colleagues[84] examined children with serologically proved HSV infection 1 to 15 years after neonatal exposure and found a higher prevalence of chorioretinal scars than noted in previous reports (28% vs. 4%). This finding suggests that HSV remains dormant in the retina and reactivates later in childhood or adulthood. Chorioretinitis, cataracts, optic atrophy, and microphthalmos have been reported.[112] Acute retinal necrosis from reactivation of HSV-2 has occurred as well.[276]

Ocular HSV infection can be seen in conjunction with a vesicular rash or disseminated disease. The differential diagnosis of ophthalmic complications from HSV includes infection with any of the TORCHS organisms. Identification of neonatal IgM antibody to HSV confirms the diagnosis of in utero infection. Demonstration of intranuclear inclusions and multinucleated giant cells in skin, conjunctiva, and oral and genital lesions may be diagnostic.

The drug of choice to treat neonatal HSV infection is intravenous acyclovir 60 mg/kg/day.[214] Conjunctival and corneal disease also can be treated by débridement and topical antivirals such as vidarabine. In neonatal HSV infection, systemic acyclovir should be given regardless of topical treatment. Early diagnosis and treatment can reduce ocular morbidity.

Varicella-Zoster Virus Infection

VZV is a DNA virus of the family *Herpesviridae;* enveloped virions are the infectious agents. Primary infection results in chickenpox, a highly communicable febrile illness with a vesicular rash that appears after 48 to 72 hours of incubation. VZV can remain dormant in sensory ganglion neurons and reactivate as herpes zoster, a painful rash in the dermatomal distribution of the sensory ganglion.

Congenital varicella syndrome is considered a rare entity. One prospective series reported a 24 percent incidence of congenital varicella with serologic or clinical confirmation of maternal infection during pregnancy. Mortality rates can be high if maternal infection develops 5 days before delivery to 2 days after delivery. Systemic complications of VZV infection include cranial nerve palsy, hemiparesis, cicatricial skin lesions, IUGR, developmental delay, seizures, neurogenic bladder, and learning difficulty.[152,210]

Ocular abnormalities in children with congenital VZV infection include chorioretinitis, cataracts, Horner syndrome, optic atrophy and optic nerve hypoplasia, retinal coloboma, and microphthalmos. The chorioretinal scars of VZV infection have a deeply pigmented center with depigmented borders or a gliotic white center with hyperpigmented edges. The neurotropic nature of VZV infection may explain the association of Horner syndrome. Ocular involvement can be unilateral or bilateral. VZV chorioretinitis affects the macula, periphery, or both.

Serologic testing for IgG and IgM antibodies to VZV, a history of maternal infection during pregnancy, and the constellation of systemic findings help establish the diagnosis. Because active infection may occur early in pregnancy, the neonate may have IgG but no detectable IgM antibodies to VZV by the time of delivery. The persistence of elevated IgG antibodies beyond 6 months, when passive immunity through maternal antibodies has waned, without evidence of primary VZV infection postnatally is a helpful indication of infection in utero.

Syphilis

Syphilis is caused by the spirochete *T. pallidum*. Acquired syphilis is a sexually transmitted chronic disease and has three stages of infection. Primary infection is characterized by painless, indurated chancres of the skin or mucous membranes at the site of inoculation. The secondary stage appears as a maculopapular rash, classically involving the palms and soles. Generalized lymphadenopathy, fever, malaise, sore throat, headache, and arthralgias can accompany the rash. Hypertrophic lesions (i.e., condyloma lata) occur in moist mucous membranes. Approximately a third of untreated cases progress to the tertiary stage, which occurs after a variable latent period that may have occasional recurrences of secondary syphilis. Transmission to the fetus can occur with any stage of maternal syphilis.[271]

Pigmentary retinopathy is the most common early ocular manifestation of congenital syphilis. Diffuse mottling in the periphery (i.e., salt-and-pepper retinopathy) is indicative of chorioretinitis in utero. Pigment clumping in the periphery usually has no effect on vision, but macular involvement can cause decreased vision. Retinal changes can appear later in adulthood, thus suggesting that inflammatory changes caused by congenital infection can occur after birth. Salt-and-pepper retinopathy is evidence of previous inflammation, and no treatment is required. Interstitial keratitis (see the discussion of stromal keratitis) is the hallmark of congenital syphilis and occurs in 75 percent of these patients.[271] It usually is not detected until late in the first decade of life. Other reported ocular manifestations include optic neuritis and iritis.

Testing the serum by nontreponemal and treponemal methods confirms the diagnosis of congenital infection. The American Academy of Pediatrics recommends physical examination, quantitative nontreponemal serologic

testing, a CSF Venereal Disease Research Laboratory (VDRL) test, long-bone radiographs, and antitreponemal IgM testing, as specified by the Centers for Disease Control and Prevention (CDC). The CDC states that congenital syphilis is presumptively diagnosed with a positive VDRL and at least one of the following: physical examination evidence of congenital syphilis, characteristic radiographic long-bone findings, VDRL-positive CSF findings, an otherwise unexplained elevated CSF protein or cell count, quantitative nontreponemal serologic titer four times greater than the mother's, or a positive fluorescent treponemal antibody absorbent FTA-(ABS) 19s IgM test.[5] Treatment is with intravenous penicillin G for 10 to 14 days.[6,170]

Endophthalmitis

Endophthalmitis is an infection within the eye that may arise endogenously during septicemia or exogenously from accidental or surgical trauma.[183,193] Sixty-two percent of cases occur after intraocular surgery, 20 percent after penetrating trauma, and 10 percent after glaucoma surgery; 8 percent result from metastatic infection.[75,222] The patient usually has severe ocular pain and visual loss at initial evaluation. Rarely, patients may be asymptomatic. Signs of endophthalmitis include conjunctival injection, vitritis, uveitis, hypopyon, and intraocular membrane formation.

Endophthalmitis is an ophthalmic emergency and necessitates immediate evaluation of aqueous and vitreous cultures and institution of intravitreal antibiotic therapy. Any significant delay in recognition and treatment of endophthalmitis can result in permanent vision loss.

Postsurgical endophthalmitis occurs in 0.086 percent of cataract operations.[2] The source of postsurgical infection may be from the eyelids, conjunctiva, contaminated instruments and irrigating solutions, or contamination by operating room personnel. The routine use of subconjunctival antibiotics after intraocular surgery does not prevent all cases of postoperative endophthalmitis. Vitreous loss, which may occur occasionally as a complication of cataract surgery, increases the risk for infection developing. Patients who have undergone glaucoma filtering surgery are particularly prone to endophthalmitis, primarily because sclerostomy is performed routinely as part of this procedure and the only remaining protection the eye has from infective organisms is a thin layer of conjunctiva overlying the sclerostomy. Local antimetabolites, often used in conjunction with glaucoma filtering procedures, predispose the conjunctiva to bleb leaks that allow direct access of microorganisms to the eye.

Endogenous (metastatic) endophthalmitis should be suspected when ocular inflammation occurs in a septicemic patient, particularly if the patient is immunocompromised or has an underlying systemic illness such as diabetes or leukemia.[28,190,204]

Posttraumatic endophthalmitis should be considered in any patient with a history of injury and visual loss. A history of a high-velocity projectile presents great concern for a penetrating injury, and apparently minor accidental ocular trauma may result in perforation of the globe with or without a retained foreign body. The likelihood of posttraumatic endophthalmitis occurring increases directly with the extent of the injury and the degree of intraocular contamination.

After the diagnosis is suspected, immediate referral to an ophthalmologist is necessary. Once the patient has been examined, a vitreous and aqueous aspirate is obtained under general anesthesia and material is evaluated with Gram and Giemsa stains. Staining with calcofluor white or acridine orange is performed if fungal infection is a concern. The material is cultured on blood and chocolate agar, thioglycolate broth, and Sabouraud agar. Vancomycin 1 mg to cover gram-positive organisms and ceftazidime 2.25 mg to cover gram-negative organisms are injected into the vitreous cavity. If fungal infection is suspected, intravitreal amphotericin B is given. Occasionally, the ophthalmologist uses intravitreal dexamethasone to control associated, intense intraocular inflammation. Gram stain results often are inconsistent with cultures.

The role of vitrectomy in postoperative endophthalmitis has been addressed in the Endophthalmitis Vitrectomy Study (EVS).[6] In eyes with better than light perception vision at initial evaluation, outcome measurements were equal between the vitrectomy group and the vitreous tap or biopsy group. In eyes with only light perception vision, the EVS found that patients who underwent immediate pars plana vitrectomy did significantly better than those who underwent vitreous tap or biopsy alone.

The most common infectious agents in endophthalmitis are *S. epidermidis*, *Bacillus* spp., *Streptococcus* spp., *S. aureus*, and various fungi. *Bacillus cereus* is isolated in 30 to 40 percent of cases and can cause severe ocular morbidity.[1,59,60,70,119] *S. epidermidis* is the predominant organism in postoperative cases, and *Streptococcus* spp. with filtering blebs and *B. cereus* are the organisms associated most frequently with penetrating trauma. Approximately 65 percent of cases are culture-positive.

Fungal endophthalmitis has become a relatively common form of endophthalmitis in childhood because of the prolonged hospital care required for severely ill immunocompromised children. The most common organism is *C. albicans*. Children with a central line catheter or receiving prolonged intravenous therapy of any type are particularly prone to infection. In patients with *Candida* endophthalmitis, the vitreous may be hazy and small, white "snowball" localizations of infected material may appear in the vitreous or on the surface of the retina. Daily careful observation may be required during intravenous amphotericin B therapy. If the endophthalmitis clears, no ocular surgical intervention is indicated. If the infection is not adequately controlled with intravenous therapy, vitrectomy with injection of intravitreal amphotericin may be required.[86]

SECTION **XII**

SYSTEMIC INFECTIOUS DISEASES

CHAPTER 62

Bacteremia and Septic Shock

Sheldon L. Kaplan • Jesus G. Vallejo

One of the most serious and potentially life-threatening infectious diseases in childhood is a bacteremic illness. Bacteremia may be caused by a wide variety of gram-positive or gram-negative microorganisms, and it may or may not be associated with a specific focus of infection, such as pneumonia or meningitis. The bacteremias that are transient and self-limited are not discussed in this chapter.

The incidence of bacteremia in children has been studied in hospital and ambulatory settings. In otherwise normal children, beyond the neonatal age group, *Streptococcus pneumoniae*, *Escherichia coli*, *Staphylococcus aureus*, group A streptococcus, *Salmonella* spp., and *Neisseria meningitidis* are the most common microorganisms causing bacteremia.[92,221] The incidence of pneumococcal bacteremia has decreased substantially since the introduction of the conjugate pneumococcal vaccine.[115,163] In contrast, methicillin-resistant *S. aureus* (MRSA) bacteremia is on the rise in children in the United States.[77] Children with underlying illnesses that depress the host response to infection may develop bacteremia caused by these same microorganisms; however, in this population of children, especially when hospitalized, Enterobacteriaceae, *S. aureus*, coagulase-negative staphylococci, and fungi are the most important organisms commonly isolated from blood cultures.[5,157] Indwelling vascular lines, urinary catheters, endotracheal tubes, and other foreign material further predispose already compromised children to nosocomial infections. The incidence of diagnosed septicemia has increased over the years, partly owing to improved medical technology and the greater numbers of individuals with immunocompromising conditions who previously would not have survived.[146,147]

Gray and colleagues[85] reported that the incidence of bloodstream infections in a pediatric intensive care unit (PICU) during a 3-year period was 39 cases per 1000 admissions. Of the episodes, 64 percent were acquired in a PICU and 20.6 percent were community-acquired infections. Gram-positive and gram-negative organisms accounted for 62 percent and 31 percent of the isolates, respectively. Yeasts were isolated in 5.6 percent of episodes. The frequency of catheter-related bloodstream infections has been decreasing in many PICUs as a result of implementing insertion and maintenance bundles.[133] Children with acquired immunodeficiency syndrome or severe immunosuppression caused by human immunodeficiency virus infection also are at increased risk for developing bacteremias caused by gram-negative bacilli, especially *Pseudomonas aeruginosa*.[175]

Using a seven-state hospital discharge database, Watson and associates[221] estimated that the U.S. age-adjusted and sex-adjusted annual incidence of severe sepsis was 0.56 cases per 1000 children, or more than 42,000 cases per year. The highest age-specific incidence occurred in infants (5.16 cases per 1000), with the incidence declining to 0.20 cases per 1000 for children 10 to 14 years old. Half of the children had underlying comorbidity, with neuromuscular, cardiovascular, and respiratory disorders being the most common.

One potential consequence of bacteremia is septic shock, a state characterized by inadequate tissue perfusion that is associated frequently with endotoxemia. Although most children with septic shock have infections caused by gram-negative enteric bacteria, *P. aeruginosa*, or *N. meningitidis*, which are organisms with endotoxin or lipopolysaccharide (LPS) within cell walls, septic shock also is associated with disease caused by gram-positive bacteria (especially *S. aureus*, *Streptococcus pyogenes*, and viridans streptococci), viruses, rickettsiae, and fungi. Community-acquired methicillin-resistant *S. aureus* (CA-MRSA) in particular has been associated with severe sepsis and septic shock in young children and adolescents.[4,82] In adults, the frequency of septic shock continues to increase as the population ages, new treatment methods including more complicated surgery and immunosuppressive agents are developed, and antibiotic resistance grows.[178]

DuPont and Spink[59] reviewed the cases of 172 children, 30 days to 16 years of age, who were hospitalized at the University of Minnesota Medical Center with gram-negative bacteremia. Shock occurred in 25 percent of the children, 98 percent of whom died. In meningococcal infections, 11 to 40 percent of children developed hypotension.[105,216] During a 10-month study period, Naqvi and colleagues[144] reported that shock occurred in 5 of 39 (13%) episodes of gram-negative bacillary sepsis, with three deaths. Jacobs and associates[98] reviewed the admissions of previously normal children to a PICU in a large children's hospital for a 30-month period. Hypotension or evidence of peripheral hypoperfusion occurred in 143 children with confirmed bacterial sepsis, mostly *Haemophilus influenzae* type b, or apparent meningococcemia. Among 1058 consecutive admissions of 916 children to a PICU in Canada from July 1, 1991, to July 31, 1992, 25 episodes (2%) of septic shock occurred.[165] During a 12-month period, 140 episodes of septicemia (135 bacterial and 5 fungal) were documented in 100 pediatric hematology-oncology patients.[4,5] Septic shock occurred in 19 percent.

The organisms and case-fatality rates in the study by Watson and colleagues[221] are outlined in Table 62-1. *N. meningitidis* and fungi were associated with the highest

TABLE 62-1 **Occurrence and Case-Fatality Rates of Selected Pathogens Among Children with Severe Sepsis Based on Age***

	<1 Yr (N = 4643)		*1-10 Yr (N = 2724)*		*11-19 Yr (N = 2308)*	
Organism	**Cases (%)**	**Case-Fatality (%)**	**Cases (%)**	**Case-Fatality (%)**	**Cases (%)**	**Case-Fatality (%)**
Neisseria meningitidis	0.3	20	8	10.4	2.3	15.1
Haemophilus influenzae	1.6	4.2	2.4	1.6	1.9	6.8
Pseudomonas	3.6	14.6	7.7	12.4	6.9	9.4

TABLE 62-2 **Consensus Definitions of Systemic Inflammatory Response Syndrome (SIRS), Infection, Sepsis, Severe Sepsis, and Septic Shock**

SIRS

The presence of two or more of the following four criteria, one of which must be abnormal temperature or white blood cell count:

1. Core temperature (rectal, bladder, oral, or central catheter probe) >38.5°C (101.3°F) or <36°C (96.8°F)
2. Tachycardia defined as more than two standard deviations above normal for age in the absence of external factors or drugs *or* otherwise unexplained persistent elevation of a 0.5- to 4-hr time period *or* for children <1 year old, bradycardia, defined as a mean heart rate <10th percentile for age in the absence of external factors or drugs or otherwise unexplained persistent depression over a 0.5-hr period
3. Mean respiratory rate more than two standard deviations for age *or* mechanical ventilation for an acute process not related to an underlying neuromuscular disease or to general anesthesia
4. Peripheral white blood cell count elevated or depressed for age unrelated to medications or >10% immature neutrophils

Infection

A suspected or proven (by culture, tissue stain, polymerase chain reaction assay) infection caused by any pathogen *or* a clinical syndrome associated with a high probability of infection

Sepsis

SIRS in the presence of or caused by suspected or proven infection

Severe Sepsis

Sepsis plus one of the following: cardiovascular organ dysfunction, acute respiratory distress syndrome *or* two or more other instances of organ dysfunction as defined in the consensus statement

Septic Shock

Sepsis and cardiovascular organ dysfunction as defined in the consensus statement

Modified from Goldstein B, Giroir B, Randoph A, and the Members of the International Consensus Conference on Pediatric Sepsis. International Pediatric Sepsis Conference: definitions for sepsis and organ dysfunction in pediatrics. *Pediatr Crit Care Med* 2005;**6**:2–8.

mortality rates. Early-onset group B streptococcal infections in neonates and overwhelming *S. pneumoniae* infections in children with splenic dysfunction or asplenia are associated with shock in a high percentage of cases. *S. aureus* or group A streptococcus may cause hypotension in a child with or without other manifestations of toxic shock syndrome.[184]

Advances in understanding of the pathogenesis and pathophysiology of septic shock with respect to the host response to infection have required that more precise clinical definitions of sepsis and expanded syndromes be developed. Much of the impetus for this effort is related to the ability to identify more readily patients with infections who may benefit from administration of newer (expensive) adjunctive measures. An American College of Chest Physicians and Society of Critical Care Medicine Consensus Conference in 1991 developed new terminology to define sepsis and its sequelae.[25] This terminology has been modified for use in children by an international consensus panel of 20 experts in sepsis and clinical research (Table 62-2).[80]

PATHOPHYSIOLOGY

The pathophysiology of bacteremia is highly variable and depends on the specific microorganism isolated, the

immune status of the host, and other factors such as the locations of indwelling catheters. Highly encapsulated organisms, such as *S. pneumoniae*, *N. meningitidis*, and *H. influenzae* type b, normally may reside in the nasopharynx and, for reasons that are poorly understood, are capable of invading beyond mucosal barriers into the bloodstream. A preceding viral upper respiratory tract infection may play some role in alterations in local host defense mechanisms that result in bacteremia.[106,131]

Using human columnar nasopharyngeal tissue in organ cultures, Stephens and colleagues[189] showed that *N. meningitidis* organisms were ingested by the columnar cells, then found within phagocytic vacuoles, and later observed within subepithelial tissues, suggesting that the meningococci had penetrated the epithelial layer. In this same model, *H. influenzae* type b organisms attach to nonciliated columnar epithelial cells and subsequently are found in the intercellular spaces in association with a preceding disruption of the tight junctions of epithelial cells.[60] After passing the mucosal barriers, *H. influenzae* type b may enter the bloodstream directly through pharyngeal blood vessels.[177] Pneumococci adhere to specific ligands on respiratory cells. The inflammatory mediators generated during viral infections upregulate platelet-activating factor receptor on respiratory cells to which the pneumococci adhere more avidly and subsequently invade.[204] Pili or adhesins of gram-negative enteric organisms seem to be important in attachment and adherence of these microorganisms to specific receptors expressed on epithelial surfaces. Pili also have been shown to be important in the pathogenesis of some gram-positive infections, such as *S. pyogenes*, group B streptococcus, and *S. pneumoniae*.[14,140]

The placement of an endotracheal tube unmasks a greater number of these receptors, presumably through increased protease activity of secretions and decreased cell-bound fibronectin, and leads to colonization of the upper respiratory tract with gram-negative organisms, which are ubiquitous in the environment of an ICU.[232] Biofilm formation on the endotracheal tube surface may contribute to the persistence of colonization.[116] Altered host defense mechanisms allow these organisms to move beyond epithelial surfaces and cause bacteremia.

The gastrointestinal and genitourinary tracts are major sources of gram-negative organisms responsible for bacteremia. These organisms first may cause localized abscesses or peritonitis if intestinal perforation occurs, or they may translocate to the intestinal mucosa, particularly when the mucosa is affected by antineoplastic agents. Viridans streptococci can cause bacteremia in a neutropenic patient with severe mucositis that develops after the patient undergoes chemotherapy.[168] Microorganisms within the bladder may ascend the genitourinary tract and presumably enter the bloodstream through the kidneys. *S. aureus* and *S. pyogenes* are common inhabitants of the skin and skin structures. Any skin wound or foreign matter within the skin tissue renders the skin more susceptible to bacterial invasion. Staphylococci have a unique capability of adhering to solid surfaces, such as catheters, which may be an important prerequisite to colonization and subsequent catheter-related bacteremia.[160]

The pathophysiology of septic shock is very complex. Septic shock associated with gram-negative organisms has been studied most extensively, especially with respect to endotoxin or bacterial LPS, which has multiple biologic effects. Bacterial LPS has three basic components, as follows:

1. Terminal side chains consist of repeating oligosaccharides that differ from strain to strain and are responsible for the antigenic specificity of the O antigens.
2. A core LPS also consists of oligosaccharides but has less diversity in structure among strains than do the terminal side chains.
3. Lipid A is very similar among the different strains and is responsible for most of the biologic activity of endotoxin.

Endotoxin shock has been the subject of intensive animal research, and much of what is known about the pathogenesis of endotoxin shock has been derived from animal models. Although septic shock in humans is not simulated precisely in these animal models for a number of reasons, including the fact that animals do not have underlying host defense defects, much of what has been learned about endotoxin shock in animals has been corroborated in the human host.

Endotoxin Shock in Animals

Many animal models of endotoxin shock employ infusions of live gram-negative bacteria, usually *E. coli*, or purified endotoxin, after which observations are made. The effects of purified endotoxin depend partly on the species of animal being studied. Models employing cecal ligation and puncture are thought to be more relevant to human disease than direct infusion of bacteria or endotoxin.[235] The effects of endotoxin in animal models are summarized in Table 62-3.

Numerous mediators induced by endotoxin play pivotal roles in the pathogenesis of endotoxin shock. Tumor necrosis factor (TNF), a polypeptide hormone, is a key cytokine mediating septic shock.[200] The tissue injury induced by TNF largely is a result of other mediators that are induced by TNF, including interleukin (IL)-1β, IL-6, eicosanoids, and platelet-activating factor.[55,96,198,201] TNF is synthesized by a wide variety of cells (including monocytes/macrophages, natural killer cells, microglial cells, and hepatic Kupffer cells) after stimulation by LPS, C5a, viruses, and enterotoxins, among other agents. TNF initiates a cascade of events that leads to endothelial cell injury, an enhanced inflammatory response, and, ultimately, the characteristic findings of endotoxic shock.

Nitric oxide (i.e., endothelium-derived relaxing factor) is the final pathway by which endogenous vasodilators stimulated by endotoxin result in hypotension from altered control of microcirculation. LPS through the release of cytokines induces a form of the enzyme nitric oxide synthase II, which leads to increased production of nitric oxide.[138] Inhibitors of nitric oxide synthase, such as N^G-monomethyl-L-arginine, can reverse or prevent hypotension in animals challenged with LPS.[130]

TABLE 62-3 **Endotoxin Shock in Animal Models**

Effects	Mediators
Cardiovascular Effects	
Decreased peripheral vascular resistance[145]	Histamine, bradykinin,[132] serotonin, complement activation, prostaglandins, anaphylatoxins
Decreased cardiac output[6,10,167]	
Depressed myocardial function[128]	
Decreased systemic blood pressure[44]	
Metabolic Effects[167]	
Hyperglycemia[49]	Hypoinsulinemia
Hypoglycemia[64]	
Increased adrenocorticotropic hormone, growth hormone, and antidiuretic hormone[227]	
Decreased calcium[234]	
Increased triglycerides[107,200]	
Decreased iron, transferrin, and zinc	
Pulmonary Effects	
Congestive atelectasis[44,94]	Polymorphonuclear leukocytes
Increased capillary permeability[94]	Polymorphonuclear leukocytes
Vasoconstriction	Thromboxane, prostacyclin
Bronchoconstriction[30]	Leukotrienes
Central Nervous System Effects	
Decreased regional and total cerebral blood flow[166]	
Increased cerebral oxygen consumption[166]	

The pathophysiology of septic shock caused by gram-positive bacteria is similar to that described for gram-negative organisms.[187] Cell wall components, such as peptidoglycan and teichoic acid, promote proinflammatory activity but are less potent than endotoxin.

Endotoxin Shock in Humans

The pathophysiology of septic shock is highly complex and is related predominantly to actions of endogenous mediators released as part of the systemic inflammatory response to an infection. The cascade of events is intertwining, with production of one cytokine stimulating the synthesis of others; synergistic, in that the activities of certain cytokines act in concert; and sometimes antagonistic, with the production of other molecules to inhibit or compete with various cytokines. This complicated response to an infectious stimulus has been studied best for LPS, but a similar series of events occurs in response to gram-positive infections. Although the best-understood system is the one that recognizes bacterial LPS, others exist for sensing the presence of bacterial peptidoglycan, DNA, lipopeptides, flagella, viral double-stranded RNA, and other conserved microbial molecules.

The first host protein involved in the recognition of LPS is LPS-binding protein. LPS-binding protein is an acute-phase protein; its role is to bring LPS to the cell surface by binding to LPS and forming a ternary complex with the LPS receptor molecule, CD14.[222,233] Formation of the complex between LPS and CD14 facilitates the transfer of LPS to the LPS receptor complex, which is composed of Toll-like receptor 4 (TLR4) and MD2. Studies over the course of several years led to the discovery of the TLR4/MD2 receptor complex as the signaling entity for LPS (Fig. 62-1).[20] MD2 is a secreted glycoprotein that functions as an indispensable extracellular adapter molecule for LPS-initiated signaling events, perhaps by aiding in ligand recognition. The resulting signal promotes mononuclear phagocytes to produce reactive oxygen molecules, cytokines, and arachidonic acid metabolites, including prostaglandin and leukotrienes. A counterregulatory protein is a bactericidal, permeability-increasing protein that is stored in the granules of polymorphonuclear leukocytes and inhibits the effects of LPS.[72]

TNF is largely responsible for the biologic effects, including fever, shock, myocardial suppression, capillary leak (i.e., endothelial damage), coagulation alterations, and metabolic changes,[35,36,132,199,205] of LPS in humans. In children, including neonates, the role of cytokines in sepsis caused by a variety of organisms, but especially *N. meningitidis*, is well documented.[31,52,78,193,216] LPS and TNF each can induce the synthesis of other proinflammatory cytokines, such as IL-1β and IL-6.[56] IL-6 levels in plasma correlate with mortality. IL-8 plasma concentrations also are increased after infusion of LPS or IL-1β.[56,86] Serum IL-8 levels in children with septic shock were predictive of outcome in one study.[188]

The anti-inflammatory cytokine IL-10 is produced after LPS is injected and inhibits the production of TNF, IL-1β, and IL-6.[126] Naturally occurring inhibitors of TNF or IL-1β are present in serum samples of patients with the sepsis syndrome.[79,207,208] IL-1 receptor antagonist (IL-1a) binds competitively to the IL-1 receptor to block the action of IL-1. Soluble TNF receptors bind to circulating TNF, which prevents its proinflammatory actions (see Fig. 62-1).

In adults, gram-negative bacteremia is followed by a decrease in systemic vascular resistance and mean blood pressure and an increase in cardiac output.[21,224] Decreased systemic vascular resistance may be accompanied by activation of the complement and kinin systems.[134] After this early phase, the blood pressure decreases further without change in the central venous pressure. Certain patients, especially children, are able to maintain their cardiac output and cardiac index, and this ability may be associated with increased rates of survival. When peripheral resistance is measured within 12 to 24 hours of the onset of shock, its decrease is significant in patients who survive compared with patients who die.[147] In contrast, cardiac output is reduced significantly in other patients; this decrease is associated with increased concentration of

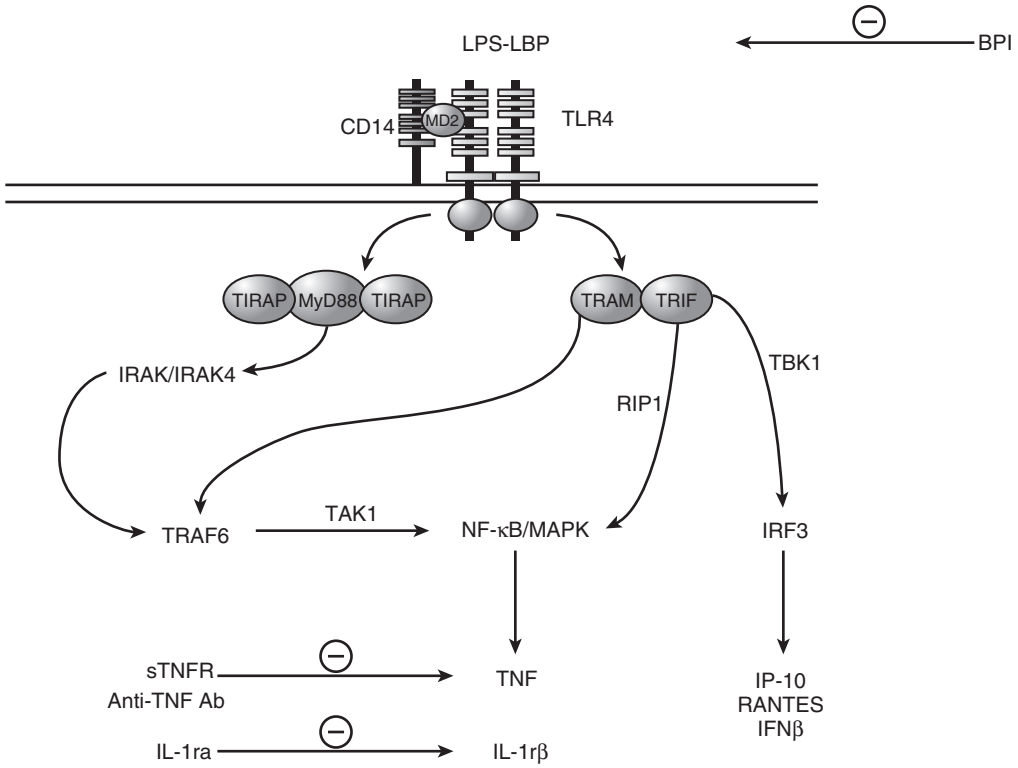

FIGURE 62-1 ■ Activation of the cytokine network by lipopolysaccharide (LPS). Circulating lipopolysaccharide-binding protein (LBP) recognizes LPS in the plasma and brings it to CD14. This aids the loading of LPS onto the LPS receptor complex, which is composed of dimerized Toll-like receptor 4 (TLR4) receptors and two molecules of the extracellular adapter MD-2. Signals activated by TLR4 can be subdivided into signals dependent on MyD88 (and Mal), which occur early (represented by the events illustrated on the left-hand side of the diagram), and signals independent of MyD88, which occur later and use the adapters TRIF and TRAM (depicted on the right). IL-1ra, interleukin-1 receptor antagonist; sTNFr, soluble tumor necrosis factor receptor.

blood lactate, decreased arterial blood pH, and decreased rates of survival.

In one small study, two distinct patterns of septic shock in children admitted to the PICU of a tertiary children's hospital were described.[29] Fifteen of 16 children with bacteremia related to central venous lines had a high cardiac index and low systemic vascular resistance. This pattern was seen in only 2 of 14 children with community-onset infections, in whom a normal or low cardiac index with variable systemic vascular resistance was typically noted.

Depression of myocardial function has been shown in adult and pediatric patients in septic shock.[63] These patients have a reduced ejection fraction, left ventricular dilation, and significantly altered ventricular performance in response to infusion of volume.[149] This depression of myocardial function is transient in survivors, however, reverting to normal within 1 to 4 days.[152] Parker and colleagues[153] found that patients who did not survive septic shock did not have left ventricular dilation or reduction in the ejection fraction. When the systemic vascular resistance index was averaged over the course of time, nonsurvivors had a significantly ($p < .05$) lower index than that of survivors of septic shock. This study included three children who were 9 to 17 years of age. Abraham and associates[1] sequentially monitored hemodynamic and oxygen transport measurements in 33 patients with septic shock. In the 24-hour period before the onset of hypotension, the survivors showed significantly greater cardiac index, left cardiac work index, oxygen delivery, and oxygen consumption than the nonsurvivors.

A circulating myocardial depressant factor in patients with septic shock was proposed more than 50 years ago, but myocardial dysfunction was not quantitatively linked to a serum factor until the late 1980s.[128,154,169] Kumar and colleagues[112] later reported that the myocardial depressant activity of sera obtained from patients with septic shock could be eliminated by the immunoprecipitation of TNF and IL-1β. Several investigators also have shown that TNF and IL-1β synergistically depress myocardial function in vitro and that this effect can be abolished by an inhibitor of nitric oxide.[34,44,151] Germane to this discussion is the observation that LPS-induced biosynthesis of TNF mRNA and protein is not strictly confined to peripheral mononuclear cells but also may occur within many different tissue compartments. Experimental studies have shown that the cardiac compartment can be a significant source of TNF during septic shock. Kapadia and colleagues[102] showed that administration of LPS leads to intramyocardial production of TNF mRNA and protein in vivo. These observations raise the possibility that the myocardial depression occurring in sepsis may develop directly in response to the compartmentalized production of TNF and other cytokines within the heart, as opposed to systemic production of these mediators by circulating mononuclear cells. TLR4 is expressed in the

heart, and investigators have suggested that it is involved in signaling the cytokine production induced by LPS within the heart.[17] The complex interactions leading to myocardial dysfunction or "septic cardiomyopathy" are incompletely understood but remain under active investigation.[70]

In children, the most comprehensive investigation of myocardial dysfunction has been in meningococcal septic shock. Thiru and coworkers[194] measured serum concentrations of the cardiac muscle–specific protein cardiac troponin I, which is released from injured cardiac myocytes, in 101 children with meningococcal septicemia. Minimum left ventricular ejection fraction was inversely related to peak cardiac troponin I levels. The degree of myocardial dysfunction, as determined by inotrope measurement, was related directly to peak cardiac troponin I concentrations. These researchers' results suggested that myocardial cell death might contribute, at least in part, to the cardiac dysfunction associated with meningococcal septic shock.

Hematologic changes, such as leukocytosis, leukopenia, and thrombocytopenia, have been observed in human volunteers after receiving an infusion of endotoxin. Thrombocytopenia commonly occurs in association with sepsis of any cause.[46] Septic shock is one of the most common causes of disseminated intravascular coagulation in children. Hageman factor (i.e., factor XII), which initiates the coagulation cascade, can be activated directly by LPS or through endothelial damage induced by bacteria.[122] In septic shock, concentrations of Hageman factor, prekallikrein, high-molecular-weight kininogen, and factor VII are decreased partly as a result of consumption.[48,101] Similarly, levels of inactivators of clotting factors, such as C1 esterase inhibitor, α_2-macroglobulin, and antithrombin III, also are diminished. Corrigan and Jordan[48] diagnosed disseminated intravascular coagulation in 24 of 26 children with septic shock and found that improvement in coagulation parameters seemed to be related most to restoration of blood pressure. A disseminated intravascular coagulation score using four components (platelet count, fibrinogen concentration, fibrin degradation products, and prothrombin time) was found to correlate with mortality in children with sepsis or septic shock.[108] Gram-negative bacteremia may be associated with a coagulopathy that is not disseminated intravascular coagulation but is characterized by prolongation of the prothrombin and partial thromboplastin times caused by a reduction in vitamin K–dependent coagulation factors.[47]

LPS or cell wall components of gram-positive organisms, through cytokine production, activate blood coagulation predominantly through the extrinsic pathway. The procoagulant state is enhanced further by decreased protein C activity, which is an important inhibitor of coagulation factors Va and VIIIa. The fibrinolytic system also is altered by endotoxemia and is mediated by plasminogen activator inhibitor–1-induced suppression. The coagulopathy associated with septic shock is characterized by a procoagulant state and inhibition of fibrinolysis.[117,119] Protein C has anti-inflammatory properties. The antithrombotic, profibrinolytic, and anti-inflammatory actions of activated protein C counteract the effects of cytokine activation, but a deficiency of protein C may be acquired during severe sepsis. Low levels of protein C have been associated with increased morbidity and mortality rates in patients with severe sepsis and septic shock.[67] For meningococcal disease in particular, dysfunction of the protein C activation pathway is a key factor in the development of the thrombosis associated with purpura fulminans. Downregulation of the endothelial thrombomodulin–endothelial protein C receptor pathway seems to be the mechanism for impaired activation of protein C during severe meningococcal sepsis.[61] Cytokine increases also lead to elevated serum ferritin levels during severe sepsis and septic shock; in one pediatric study levels above 500 ng/mL were associated with greater mortality.[74]

LPS can activate the complement cascade by the classic or the alternate pathway. Significantly depressed concentrations of C3 occur in patients with bacteremia and hypotension compared with normal individuals or with patients with uncomplicated bacteremia, and C3 is activated primarily by the alternate pathway.[62,101,124] In patients with bacteremia and hypotension, C1, C4, and C2 levels were not depressed significantly from values found in normal controls or in normotensive patients with bacteremia. In contrast, C3, C5, C6, C9, properdin, and factor B levels were decreased significantly ($p < .05$) in bacteremic patients with shock. In children with meningococcal disease, Tubbs[203] found a mean C3 concentration (as a percentage of normal values) of 132 ± 21 percent for survivors versus 91 ± 21 percent for nonsurvivors. The C3 levels did not correlate with endotoxin levels in sera.

Many metabolic alterations have been documented in the human host during endotoxin shock. Hyperglycemia followed by hypoglycemia can complicate the shock state induced by sepsis.[64,72,135,149] Whole-body use of glucose is increased during sepsis, which probably is cytokine mediated.[136,150] Glycolysis and gluconeogenesis are increased, but insulin resistance occurs in skeletal muscle. Children with underlying liver disease or with reduced glycogen stores are most likely to develop hypoglycemia during septic shock. Lactic acidosis develops as a result of poor tissue perfusion and cellular hypoxia. Lactic acid concentrations are increased in nonsurvivors and patients with poor or low-flow cardiac output during sepsis.

In clinical studies, Clowes and associates[43] identified a subgroup of patients with low-flow septic shock in whom concentrations of serum insulin were lower than concentrations in a control population. In children with meningococcal sepsis, van Waardenburg and colleagues[213] found higher blood glucose concentrations and significantly lower insulin levels on day 2 or 3 of hospitalization in children with shock compared with children without shock. Levels of plasma insulin and soluble TNF receptor–75 were inversely correlated in these children. Their findings were consistent with the inflammatory response inhibiting insulin secretion. In another study of meningococcal sepsis, both insulin resistance and beta cell dysfunction contributed to the hyperglycemia that occurred in a third of the children.[214]

Hypocalcemia and decreased serum ionized calcium concentrations occur frequently during bacterial sepsis.

In one study, 12 (20%) of 60 critically ill adults with bacterial sepsis had hypocalcemia.[234] The mortality rate in the hypocalcemic patients was 50 percent compared with 30 percent in the patients who were normocalcemic. Cardenas-Rivero and associates[38] studied calcium homeostasis in 145 children admitted to a PICU. Of 8 children with confirmed sepsis or meningitis (or both) not caused by *H. influenzae* type b, 7 had hypocalcemia and 6 of the 7 had ionized hypocalcemia. Five of the 6 children with ionized hypocalcemia had inappropriately normal concentrations of parathyroid hormone, which suggests that transient hypoparathyroidism occurs in some children with sepsis. Hypocalcemia also occurs commonly in patients with toxic shock syndrome.[226] In women with toxic shock syndrome and hypocalcemia, serum concentrations of calcitonin are elevated by unknown mechanisms.[40] Hypocalcemia and elevated calcitonin concentrations also have been documented in children with fulminant meningococcemia.[120]

Procalcitonin levels are elevated in several conditions associated with systemic inflammatory response syndrome, including sepsis, and have been proposed as adjunctive laboratory tests for the early detection of, and indicators for prognosis of, meningococcal disease and many other infections.[39] These changes in calcium levels are especially critical because the level of ionized calcium and cardiac output in septic shock can be correlated.[231] Other metabolic changes may occur during septic shock in humans, as follows:

1. Increased concentrations of cortisol and growth hormone (including in neonates)[196,217]
2. Relative adrenal insufficiency by adrenocorticotropin testing[90]
3. Depression of triiodothyronine and thyroxine levels related to poor nutrition[173]
4. Elevations in total concentrations of amino acid in plasma and the preferential use of branched-chain amino acids as an energy source for skeletal muscle[136]
5. Muscle proteolysis, possibly induced by one or more circulating agents in the plasma of patients with serious infections[42]
6. Elevations in concentrations of plasma thromboxane, which are observed in nonsurvivors of septic shock[171]
7. Elevations in concentrations of triglycerides and free fatty acid during gram-negative bacteremia[73,107]
8. Altered zinc homeostasis[229]

Liver dysfunction is an important aspect of endotoxin shock in adults. Banks and colleagues[12] found that clinical jaundice was apparent in 63 percent of their patients with septic shock, that it was found more commonly in nonsurvivors than in survivors, and that the degree of biochemical liver abnormalities was related to the duration of shock. Postmortem findings included focal liver necrosis, Kupffer cell hyperplasia, portal tract inflammation, venous congestion, and intrahepatic cholestasis.

Adult respiratory distress syndrome (ARDS), or shock lung, is a major complication of septic shock in children.[97,162] The lungs of children with ARDS have characteristic changes consisting of increased lung weight reflecting congestion and atelectasis, alveoli lined with hyaline membranes, microthrombi, hemorrhage, and interstitial edema.[97] Increased capillary permeability and intrapulmonary shunts have been documented in patients with ARDS.[50] C5a, a potent chemotactic factor, causes aggregation of polymorphonuclear neutrophils, is elevated in the sera of patients who ultimately develop ARDS, and is found in increased concentrations in bronchoalveolar lavage fluid obtained from patients with ARDS.[87,174] Leukocyte aggregates are thought to be trapped in lung tissue and may cause damage to the endothelium of the pulmonary microvasculature through the release of oxygen radicals, lysosomal enzymes, and products of arachidonic acid metabolism. Although neutrophils play a critical role in the pathogenesis of ARDS, other factors also are important, considering that ARDS can develop in patients who are neutropenic.[148,225] Thromboxane, platelet-activating factor, fibrin, and other substances contribute to the lung injury in ARDS.[176]

The effects of endotoxin shock on the central nervous system have not been studied carefully in humans.[84] The encephalopathy associated with sepsis seems to be caused partly by altered phenylalanine metabolism; concentrations of phenylalanine and its metabolite, phenylacetic acid, are increased in the sera and cerebrospinal fluid of septic adults who are stuporous or comatose.[137]

Endotoxin has been implicated in the pathogenesis of acute renal failure associated with sepsis. Wardle[218,219] showed that 12 of 16 patients with acute tubular necrosis had endotoxemia. Renal arterial blood flow and renal vascular resistance are decreased significantly in baboons 2 to 4 hours after infusion of endotoxin. Inadequate perfusion pressure was associated with renal ischemia and negligible urine output in these animals shortly after administration of endotoxin.[181] Pathologic examination of the kidneys revealed focal necrosis of the proximal tubular epithelium, eosinophilic casts within proximal and distal tubules, and microthrombi in the glomerular capillaries. Endothelin, a potent vasoconstrictor peptide produced by endothelial cells, is elevated in concentration in the plasma of patients with septic shock. Because endothelin contributes to the regulation of regional blood flow, elevated levels suggest that it may relate to renal vasoconstriction and dysfunction.[215]

Endotoxin can be measured in the plasma of patients with gram-negative bacteremia as well as in patients with other infections, even upper respiratory tract infections.[53] The presence of circulating endotoxin does not mean that bacteremia is present or ever has occurred because endotoxin presumably may be "absorbed or leak" into the circulation from the gastrointestinal tract.[118,192,202] Endotoxemia may be a valid indicator, however, of impending gram-negative septicemia in febrile patients.[209] Preformed antibody to LPS or lipid A is associated with protection against shock and death caused by gram-negative bacteremia in adults. McCartney and colleagues[126] detected endotoxin in the blood (after chloroform extraction) of patients with gram-negative septic shock; all 18 patients with persistently positive endotoxin assays died. In contrast, 9 patients who initially had endotoxemia but subsequently had negative assays survived. Other studies confirm the association between

endotoxemia and outcome.[125,210] Evidence exists that human endotoxin is cleared from the circulation by the liver and can be detoxified by neutrophil enzymes (i.e., acyloxacyl hydrolases).[123,141]

The sequence of events in the evolution of endotoxin shock has been outlined by several investigators.[145] Bacteria, endotoxin, or other bacterial products stimulate the production of TNF and other cytokines, which in concert with endotoxin set off a whole series of events. Potent mediators, including C3a, C5a, eicosanoids, platelet-activating factor, histamine, and myocardial depressant substance, are released. Potent vasodilators cause peripheral vasodilation, and decreased systemic peripheral resistance leads to pooling of blood and decreased venous return to the heart. Mean blood pressure may be low, or it may be normal if cardiac output increases sufficiently to compensate for these alterations despite depression of ventricular function. The central venous pressure, which partially depends on myocardial performance, may be low or in the normal range.

If intravascular volume is increased by the administration of sufficient fluids, shock may be prevented or corrected. Continued hypotension and diminished perfusion pressure may lead, however, to cellular hypoxia and increased production of lactic acid from pyruvate. The microcirculation is altered by local tissue acidosis. Capillary beds become congested, and intravascular fluid may leak into the interstitial spaces. Increased secretion of catecholamine leads to arteriolar and venular constriction and increased peripheral resistance. Pooling of blood is enhanced, which leads to a further diminution in venous return and a reduction of cardiac output. Oliguria, coagulation abnormalities, and additional metabolic alterations indicate multiple organ system failure and presage the death of the patient.

Wong et al.[228] have studied the genome level expression profiles of children with sepsis and septic shock. Multiple gene networks, primarily related to inflammation and immunity, were affected over time and were differentially regulated.[182] These investigations have led to the identification of three subclasses of distinct gene expression profiles; higher mortality is associated with one of these subclasses.[230] This type of classification scheme might be able to identify patients at the time of admission who are at greater risk for poor outcomes and who would be optimal candidates for studying newer interventions or strategies for treating children in septic shock.

CLINICAL PRESENTATION AND DIAGNOSIS

The signs and symptoms of bacteremia vary, greatly depending on the age and underlying disease of the patient, the duration of illness, and the specific microorganisms. Young, otherwise healthy children aged 3 months to 3 years may present with fever and evidence of an upper or lower respiratory tract infection or no focus of infection and yet have unsuspected bacteremia. Most studies indicated that the risk of developing bacteremia increases as the body temperature increases; and in the unimmunized child, almost 25 percent of these children may be bacteremic after the temperature exceeds 41°C [105.8°F].[15] In a previously healthy child, the persistence of irritability and the inability to console the child despite optimal environmental conditions have been proposed as key points in the physical examination that should alert the clinician to the possibility of a serious infection, such as bacteremia or meningitis.[125,185]

Underlying illnesses with splenic dysfunction place a child at increased risk for serious infections caused by encapsulated organisms, whereas children with leukemia or other immunosuppressive diseases or children in the ICU are more likely to be infected with gram-negative bacilli or *S. aureus*. A history of diarrhea may suggest *Salmonella* spp. as a possible cause of illness. Preceding skin infections or wounds are important clues to infection caused by *S. aureus* or group A streptococcus. An indwelling vascular catheter may precipitate overlying erythema in a patient with evidence of phlebitis proximally. Gram-positive cocci, gram-negative bacilli, and yeast can be associated with catheter-related sepsis. Toxic shock syndrome should be considered in a hypotensive girl or woman with a recent menstrual period and history of tampon use, although toxic shock also is associated with *S. aureus* sepsis in males and nonmenstruating females.[82,184] Evidence of osteomyelitis, with or without venous thrombosis, is a very common finding in staphylococcal sepsis. Intra-abdominal sources of infection increase the likelihood of developing anaerobic bacteremia.

Petechiae may be associated with many microorganisms, especially invasive disease caused by *N. meningitidis*.[211] Purpura is an ominous finding and frequently is associated with overwhelming infection caused by *N. meningitidis*, *S. pneumoniae*, and *H. influenzae* type b. *P. aeruginosa* is associated specifically with erythema gangrenosum.[57] Almost half of children presenting with erythroderma (diffuse erythema) either had shock at presentation or developed shock in one study.[33,38] Other skin and soft tissue manifestations of gram-negative sepsis include bullous lesions, cellulitis, fasciitis, thrombophlebitis, and symmetric peripheral gangrene with disseminated intravascular coagulation.[142] Signs of meningeal irritation or increased intracranial pressure are important because they may modify the approach to management of fluids in a child in shock.

The onset of bacteremia may be heralded by chills, fever, nausea, vomiting, diarrhea, rashes, and petechiae. Initially, the skin feels warm and appears flushed. A change or impairment in mental status may be the first clue to the presence of shock. Hyperventilation also may develop before the onset of clinical shock occurs, which can alert the physician to impending circulatory insufficiency.[22] In time, cold, clammy extremities; a weak pulse; tachycardia; tachypnea; hypotension; and oliguria may occur. The skin over the extremities, the tip of the nose, and the earlobes especially are prone to cyanosis. Auscultation of the lungs may reveal rales, indicating pneumonia or pulmonary edema. Abnormal distention or tenderness to palpation and guarding may be evidence of peritonitis. Costovertebral angle tenderness suggests acute pyelonephritis as a source of bacteremia.

The physician must distinguish among the following three main types of shock in children:

1. *Hypovolemic shock*, such as occurs with blood loss, fluid and electrolyte loss, adrenal insufficiency, or other causes
2. *Cardiogenic shock*, which is associated with drug intoxication, cardiac surgery, arrhythmias, and pericardial tamponade, among other causes
3. *Distributive shock*, which indicates abnormal distribution of blood flow leading to inadequate tissue perfusion (e.g., septic shock, anaphylaxis)

The laboratory evaluation of a child with bacteremia, septic shock, or both conditions should provide information concerning the cause and the data required for optimal supportive management. Several studies showed that a total white blood cell (WBC) count exceeding 15,000 cells/mm^3 in a 3- to 36-month-old child who has not been immunized with conjugate vaccines and with a temperature greater than 39° to 40° C [102.2° to 104° F] and without a focus of infection is an indication that the child is at increased risk for having bacteremia, especially pneumococcal bacteremia.[13,18] Since the introduction of the pneumococcal conjugate vaccine, pneumococcal bacteremia in this scenario has been greatly reduced.[92,180,191] Elevated erythrocyte sedimentation rates and C-reactive protein levels also have been suggested as useful screening tools for detecting serious bacterial infections. A low peripheral WBC count also may suggest septicemia and commonly is observed during episodes of overwhelming bacteremic illnesses.

Procalcitonin levels are elevated in bacteremic children and are related to the severity of illness, such as organ failure and even mortality.[88,113] Commercial kits for the rapid measurement of concentrations of procalcitonin are available. Hemoglobin and hematocrit results should help differentiate between septic and hemorrhagic shock. Examination of the peripheral smear may disclose evidence of splenic dysfunction (i.e., Howell-Jolly bodies) or fragmented red blood cells, as seen in disseminated intravascular coagulation. Thrombocytopenia, prolongation of prothrombin time and partial prothrombin time, and the presence of fibrin split products are consistent with disseminated intravascular coagulation.

Hyponatremia is a common finding. Concentrations of serum bicarbonate may be depressed, which may signify a state of metabolic acidosis. Elevated lactic acid concentrations result from inadequate tissue perfusion and in some reports have been significantly greater in nonsurvivors or patients with low-flow states than in survivors or patients with high-flow shock.[43] In pediatric studies, serial lactate levels showing normalization are associated with recovery.[58] Hyperglycemia or hypoglycemia may be encountered. In one study, serum glucose levels greater than 178 mg/dL were associated with a greater risk of death caused by septic shock.[27] Transaminase levels may be elevated and presumably reflect cellular injury. Serum calcium concentrations (preferably ionized calcium levels) should be checked periodically because hypocalcemia may interfere with optimal myocardial function.

A chest radiograph may reveal a pulmonary source of infection or show a secondary pulmonary manifestation of an invasive infection such as pneumonia or septic emboli in children with staphylococcal sepsis.[81] Arterial blood gases obtained early in endotoxin shock usually reveal hypocapnia and normal to elevated pH.[22,23] At this point, the patient has a mixed metabolic acidosis and respiratory alkalosis. If the shock state progresses, the metabolic acidosis becomes so severe that respiratory compensation is ineffective, and the patient becomes acidotic. In some patients, respiratory acidosis accompanies metabolic acidosis. In either case, decompensated metabolic acidosis in a patient with septic shock is associated with a grave prognosis. A major consequence of ARDS is hypoxemia. For patients with ARDS, the chest radiograph characteristically shows bilateral and diffuse hazy infiltrates; opacification of all lung fields usually is seen during the late phases of ARDS. Positive fluid balance contributes to the pulmonary dysfunction in patients with acute lung injury, including those related to sepsis.[69]

Concentrations of blood urea nitrogen and serum creatinine may be elevated. Jones and Weil[100] found that the ratio of urine to plasma osmolality was the most valuable indicator of renal impairment in adult patients with shock. When this ratio was greater than 1.5, the likelihood of developing progressive renal failure was remote. A urine osmolality value greater than 400 mOsm/kg also indicated adequate renal function. Gene microarray studies may identify novel biomarkers that identify a patient in septic shock who is at greater risk for acute kidney injury.[16] Many WBCs or WBC casts in the urine may suggest the genitourinary tract as the source of bacteremia. If one or more gram-negative rods are seen on the Gram stain of unspun urine, more than 10^5 colony-forming units/mL of bacteria are likely to be present.

Isolating the organism responsible for bacteremia or septic shock is important for documenting the infection and for providing optimal antimicrobial therapy. With instruments that continuously monitor growth in the blood culture bottles, growth can be detected sooner than if the bottles are inspected just once or twice daily. Before the use of the pneumococcal conjugate vaccine became routine, many authorities recommended that a blood culture be obtained in a 3- to 36-month-old child with temperature greater than 39° to 40° C [102.2° to 104° F] and a total WBC count greater than or equal to 15,000 cells/mm^3 and without a specific focus of infection. In this way, instances of "unsuspected" or "outpatient" bacteremia could be identified. In an outpatient setting, almost 90 percent of blood cultures growing true pathogens were positive within 24 hours of incubation using a continuously monitored system.[129] This approach is now less useful in the era of administration of pneumococcal conjugate vaccine to young infants.[99]

In an infant who has received three or more doses of the conjugate pneumococcal vaccine, the likelihood of developing invasive pneumococcal infection is reduced approximately 90 percent. The proportion of children with high fever without localizing findings and a WBC count of 15,000/mm^3 or greater who might have occult pneumococcal bacteremia may be less than 1 percent, a level that no longer justifies this approach. Most organisms isolated from blood cultures in these patients are

now more likely to be a contaminant than a true pathogen. Currently, the approach to a febrile child without a source has changed in many emergency departments such that more selective criteria for obtaining blood cultures are being developed.

When appropriate, cerebrospinal fluid, urine, and other pertinent sites should be cultured before initiating antibiotic therapy, if possible. When an intra-abdominal source of infection is likely, blood and other cultures should be processed anaerobically. Gram stain or acridine orange stain of a buffy coat smear of peripheral blood may reveal evidence of the causative microorganism, especially in an overwhelming infection.[110] Gram stain of material obtained from petechial or purpuric lesions may show gram-negative diplococci suggestive of meningococcus. Polymerase chain reaction for detecting *N. meningitidis* is available in selected laboratories and may be the only method by which infection is documented when cultures are sterile. Bacterial polysaccharide antigens can be detected rapidly in many body fluids by latex agglutination tests. Rapid diagnostic procedures for evaluating outpatients with suspected bacteremia are unreliable. Pneumococcal antigenuria is not detected readily when bacteremia occurs without a specific focus of infection. The value of assays for detecting circulating endotoxin is unclear.

TREATMENT

The initial selection of antibiotics for administration to a child with suspected bacteremia is based on the clinical situation (Table 62-4). If untreated initially, children with occult bacteremia are at risk for developing serious complications, such as meningitis or pneumonia.[121,143] Empirical antibiotic therapy for children who are selected carefully and observed seems reasonable.[13,15,68]

TABLE 62-4 **Empirical Antibiotic Regimens for Septic Shock in Infants and Children Under Selected Clinical Circumstances**

Circumstances	Antibiotics
Normal Child	
Skin findings suggesting meningococcemia or preceding skin trauma or varicella	Cefotaxime or ceftriaxone + vancomycin ± nafcillin
Urinary tract source	Cefotaxime or ceftriaxone + aminoglycoside
Intra-abdominal source	Clindamycin + gentamicin + piperacillin-tazobactam
Immunocompromised Child	
Malignancy or immunodeficiency or neutropenia or central line	Vancomycin + aminoglycoside + ticarcillin-clavulanate or piperacillin-tazobactam or ceftazidime
Asplenia or splenic dysfunction	Vancomycin + cefotaxime or ceftriaxone

In children who have not received more than two doses of the pneumococcal conjugate vaccine, one approach may be to obtain a blood culture from children aged 3 to 36 months with a temperature of 39° C [102.2° F] or greater who have no focal findings and whose peripheral WBC count is greater than or equal to 15,000/mm^3. In such patients, the decision to administer antibiotics expectantly may be based on several factors, especially the ability of the parents to observe the child and communicate this information back to the physician in a timely manner. Ceftriaxone given parenterally, an oral agent such as amoxicillin and amoxicillin-clavulanate, or other oral antibiotics can be administered. If treatment is initiated, a properly collected urine specimen for urinalysis or urine culture also should be obtained so that a urinary tract infection would not be treated inadvertently, because a urinary tract infection is now the most common serious bacterial infection in young children with fever without a source.[99] Occult bacteremia caused by *S. pneumoniae* intermediate or resistant to penicillin or intermediate to ceftriaxone in an otherwise normal child should resolve with any of the options noted earlier.[104] This approach probably is less useful in an infant or child who has received three or more doses of the conjugate pneumococcal vaccine.

Children who subsequently are determined to have *S. pneumoniae* bacteremia and who have been treated with antibiotics expectantly need to be reevaluated as soon as the results of the blood cultures are known. If the child appears well and has been afebrile for at least 24 hours and if the parents can observe the child carefully and are able to communicate frequently with the physician, outpatient management can be continued. For children who were not treated initially, who remain febrile, and who are called back to be reevaluated for a positive blood culture, a parenteral dose of antibiotics is recommended.[11] Close contact with the parents and patient is mandatory no matter how these children are managed initially. Hospitalization for intravenous antibiotics is indicated if the child appears "toxic" or has other signs suggesting a serious infection.

For children with suspected bacteremia who are ill and require admission to the hospital, antibiotics are selected to cover the most serious organisms causing that infection. In normal children aged 3 months or older, a combination of nafcillin 150 to 200 mg/kg/day or another semisynthetic antistaphylococcal penicillin plus cefotaxime 150 to 200 mg/kg/day or ceftriaxone 75 to 100 mg/kg/day covers most of the likely pathogens (e.g., *S. pneumoniae*, *S. aureus*, *S. pyogenes*, *N. meningitidis*, and *H. influenzae* type b). In areas of the world where CA-MRSA is a problem, an agent effective against MRSA should be included in the initial empirical regimen.[91,103] Vancomycin 45 to 60 mg/kg/day is the gold standard for treating infections caused by MRSA. Whether adding an aminoglycoside or rifampin to vancomycin is beneficial is unclear. Although most CA-MRSA isolates are susceptible to clindamycin, this agent is not generally recommended alone for bacteremic illness because it is not bactericidal. Some experts recommend adding clindamycin to vancomycin or nafcillin theoretically to reduce toxin production. This

reduction occurs in vitro, but no clinical data indicate that this approach leads to a decrease in the incidence of morbidity or mortality.[190]

Treatment of bacteremia associated with a genitourinary or gastrointestinal source requires antibiotics to which gram-negative enteric agents are susceptible. In such cases, initial therapy could consist of an aminoglycoside with an additional antibiotic active against anaerobes, such as clindamycin, metronidazole, ticarcillin-clavulanate, or piperacillin-tazobactam, for a gastrointestinal focus of infection. Extended-spectrum cephalosporins, such as cefotaxime or ceftriaxone, are the most commonly recommended drugs for treating serious gram-negative enteric infections. Optimal management of intra-abdominal or other abscesses usually requires surgical drainage, which should be undertaken as soon as the child's condition allows.

Immunosuppressed children or children in the ICU with serious illnesses require a different initial approach to suspected bacteremia. Gram-negative enteric agents, *P. aeruginosa*, *S. aureus*, and coagulase-negative staphylococcus are likely to be isolated from these patients. Empirical therapy for nosocomial infection is based on the current antibiotic susceptibility pattern within the hospital.[197] *E. coli*, *Klebsiella* spp., and *Enterobacter* spp. are among the most common organisms causing bacteremia in patients in the PICU.[172] *E. coli* and *Klebsiella* spp. frequently produce β-lactamases that lead to resistance to ticarcillin or piperacillin. Generally, a combination of an antistaphylococcal semisynthetic penicillin or vancomycin (if a central line is present) or, if MRSA is a relatively common nosocomial pathogen, an aminoglycoside and an extended-spectrum penicillin (e.g., ticarcillin-clavulanate, piperacillin-tazobactam) or a third- or fourth-generation cephalosporin (cefotaxime, ceftazidime, cefepime) is administered initially until a specific pathogen is isolated. Broad-spectrum penicillins and aminoglycosides frequently exhibit synergy in vitro against gram-negative organisms, especially against *P. aeruginosa*.[183] In critically ill patients, a synergistic combination of antibiotics may be beneficial for treating bacteremia caused by *P. aeruginosa* or *Klebsiella* spp., although this subject remains controversial.[93,111,159] Combination therapy may be most helpful in the neutropenic patient with bacteremia, especially due to *P. aeruginosa*.

After a specific organism is identified and antibiotic susceptibilities are known, the most appropriate agent is selected. If *E. coli* or *Klebsiella* spp. are isolated, these organisms can produce extended-spectrum β-lactamases. With the current Clinical and Laboratory Standards Institute breakpoints, the extended-spectrum β-lactamase–producing bacteria should be detected.[41,156] If an organism is identified, treatment with an extended-spectrum cephalosporin (e.g., cefotaxime, ceftriaxone, ceftazidime) is not recommended.[158] In this case, a carbapenem, such as imipenem-cilastatin or meropenem, is advised.[158]

Enterobacter spp., *Citrobacter* spp., and *Serratia marcescens* may hyperproduce β-lactamase enzymes or be induced to hyperproduce these enzymes and are resistant or can become resistant to the extended-spectrum cephalosporins.[161] In many institutions, a high percentage of these isolates are resistant to ceftazidime.[32] Cefepime may be more active than is ceftazidime or cefotaxime against *Enterobacter* spp. and other Amp C, β-lactamase enzyme–producing, gram-negative bacilli.[179] A carbapenem with an aminoglycoside is the regimen recommended for treating infections caused by these isolates when resistant to the third-generation cephalosporins.

In these patients, rapidly achieving therapeutic aminoglycoside levels in the plasma is important.[139] Serum concentrations of the aminoglycoside should be measured within 24 hours of initiation of therapy to ensure that therapeutic concentrations have been reached. Higher doses of antibiotics than normally administered may be required in some patients.

Antibiotics should be administered as soon as the diagnosis of septic shock is suspected. The selection of antibiotics is the same as that for bacteremia. If *S. aureus* is suspected among the potential causes of septic shock, antibiotic therapy is complicated by two factors: MRSA may make up more than 50 percent of community-acquired isolates[103] and nafcillin or oxacillin is superior to vancomycin for the treatment of serious infections caused by MRSA.[83] Nafcillin or oxacillin plus an aminoglycoside may be synergistic against staphylococci, but adding an aminoglycoside increases the risk for nephrotoxicity to develop. Some authorities include nafcillin or oxacillin plus vancomycin plus gentamicin in the initial empirical therapy of patients with life-threatening infections possibly caused by *S. aureus*.[7] Combination empirical antibiotics appear to be advantageous because it is more likely that an antibiotic active against the causative pathogen will be administered compared with empirical monotherapy and not because of potential synergy.[54]

The management of septic shock is directed toward three main objectives: (1) control of the infectious process, (2) restoration of adequate tissue perfusion, and (3) maintenance of efficient respiratory function. Providing aggressive fluid resuscitation early in the emergency center proved to be one factor in decreasing the length of hospital stay in one study.[114] Details of management have been the subject of numerous reports.[37,109,178] The reader is referred to these reviews for expert detailed guidance in the fluid management, use of vasoactive agents, and respiratory treatments in children with septic shock. Providing aggressive fluid resuscitation early in the emergency center proved to be one factor in decreasing the length of hospital stay in one study.

The benefits of therapy with high doses of corticosteroids in the treatment of endotoxin shock remain unproved. Extensive experimental data document the salutary hemodynamic, metabolic, microcirculatory, and cellular effect of corticosteroids in laboratory models of endotoxin shock.[95,104] High-dose corticosteroids have never been found to be efficacious, however, in randomized controlled trials conducted in adults with severe sepsis or septic shock.[26,186]

On the basis of these studies, the routine use of high-dose corticosteroids in patients with severe sepsis or septic shock is not recommended. Results of randomized studies enrolling adults suggested that lower stress doses of hydrocortisone might be beneficial in managing patients with septic shock.[24,28] However, it is not clear if

TNF, tumor necrosis factor.

there is a survival benefit at 28 days.[155] The role of low-dose hydrocortisone in children with septic shock remains controversial.[9,212] In one pediatric study the addition of fludrocortisone, a mineralocorticoid given enterally, to parenteral hydrocortisone was associated with shorter duration of norepinephrine support but more hypokalemia in children with sepsis.[89] Randomized studies are needed to clarify the role of stress doses of hydrocortisone in children with septic shock.

Every effort should be made to ensure an adequate airway, which may require periodic suctioning if the patient is unable to clear pooled secretions. Humidified oxygen in concentrations required to maintain an adequate partial pressure of oxygen should be provided early. The method of oxygen administration (e.g., mask, ventilator) depends on the clinical state of the patient. Intubation and assisted ventilation are indicated if the child shows evidence of impending respiratory failure.

ARDS, usually appearing within 2 days after the onset of shock, may complicate the respiratory and fluid management.[97] Pulmonary edema, atelectasis, decreased pulmonary compliance, and ventilation-perfusion abnormalities are some factors that can lead to inadequate oxygenation. Administration of excessive fluids may contribute to ARDS. The central venous pressure may remain normal, despite the presence of pulmonary edema. Positive end-expiratory pressure, oxygen, and careful attention to cardiovascular parameters are the mainstays of therapy for ARDS.[97,162,176]

The general supportive care of a child with septic shock includes attention to nutritional and metabolic requirements.[170] Parenteral alimentation may be the only means by which to provide nutrition, although the optimal amount and composition of elemental nutrients for children with septic shock are unknown. Hypocalcemia should be corrected. Platelet transfusions or fresh-frozen plasma may be necessary to correct coagulopathies. Continuous venovenous hemofiltration with or without dialysis may be instituted for complications of renal failure, such as fluid overload with pulmonary edema or hyperkalemia. Children who have acute renal failure complicating severe septic shock have a significantly higher mortality rate than children without acute renal failure.[164]

Investigative Therapies

Based on the evolving understanding of the pathophysiology of septic shock, many large, randomized, double-blind, multicenter trials have been conducted to assess the efficacy of agents that neutralize or counteract toxins or cytokines that are important in the evolution of septic shock. These immunomodulating strategies have been used on the basis of experimental data from animal studies. The conditions seen in experimental animal models of sepsis do not reflect the pathophysiologic situation seen in patients with severe sepsis or septic shock, however, which has led to many negative clinical trials (Table 62-5). One interesting newer approach is the development of endotoxin removal devices that are being evaluated to assess their potential as adjunctive measures to improve the outcome of patients with septic shock.[51]

Intravenous immunoglobulin is recommended for adjunctive therapy for patients with toxic shock syndrome caused by either group A streptococcus or *S. aureus* that is not responding to aggressive therapy after several hours or after appropriate drainage of focal infections.[8] The value of intravenous immunoglobulin in the treatment of septic shock caused by *S. aureus* infection but not associated with toxic shock syndrome has not been established.[76] Investigative antibodies such as tefibazumab (Aurexis), a monoclonal antibody directed against clumping factor A, an adhesin on the surface of *S. aureus*, have not been shown to improve the outcome of adults with *S. aureus* bacteremia.[223] Early phase II clinical trials of eritoran tetrasodium, a TLR4 antagonist, for the treatment of severe sepsis seemed promising; however, a recently completed phase III randomized trial did not improve the primary end point of 28-day all-cause mortality in 2000 adult patients with severe sepsis.[195*]

Plasmapheresis, exchange transfusions, and extracorporeal membrane oxygenation are heroic measures that seem to be beneficial in selected patients not responding to standard management.[18,75,206] These procedures may be considered for such patients when, in the opinion of experienced clinicians, their use is justified and they are the last hope for a successful outcome.[71]

PROGNOSIS

The morbidity and mortality rates for septic shock in children vary with age, the presence or absence of underlying diseases, and the specific microorganisms responsible for the septicemic state. DuPont and Spink reported a 98 percent mortality rate in their series of children with septic shock and gram-negative bacteremia. Jacobs and colleagues reported a 9.8 percent case-fatality rate for otherwise normal children with septic shock. In the pediatric HA-1A study, the overall mortality rate for severe sepsis or septic shock was 31 percent. The overall mortality rate for children with meningococcal infection was 8 percent in a 10-center surveillance study. For the seven-state sepsis cohort, the overall mortality rate was approximately 10 percent. Much progress has been made in the treatment of sepsis and septic shock since the report of Dupont and Spink was published. As with many infections, prevention is more desirable than is treatment. Careful attention given to sterile techniques for insertion and maintenance of intravascular or other lines and other procedures is crucial and may prevent some episodes of bacteremia and septic shock.

CHAPTER 63

Fever Without Source and Fever of Unknown Origin

Debra L. Palazzi

Petersdorf and Beeson[81] in 1961 proposed that the term *fever of unknown origin* (FUO) be reserved for persons with an illness persisting for 3 or more weeks and accompanied by temperatures higher than 38.4° C (101.2° F) on at least several occasions. They further specified that the cause of the fever should remain undetermined after at least 1 week of investigation in the hospital. Although this definition was arbitrary, it was useful at that time, when many of the diagnostic tests now in routine use were unknown. The purpose of their precise definition was to explore the cause of fever in this select group of adult patients and to permit comparison of data from different investigations. This exacting definition probably never was applied rigorously in pediatric practice. In children, the term *fever of unknown origin* should be reserved for fever of at least 8 days' duration and for which no diagnosis is apparent after the initial workup in the hospital or as an outpatient.

Many investigators prefer using the term *fever without source* (FWS) for fever of recent onset with no adequate explanation determined by the history or physical examination. The distinction between FUO and FWS is of more than academic interest for several reasons. First, although overlap exists, the differential diagnoses of these clinical conditions are distinct, and the most frequent causes of one can be different from the most frequent causes of the other. Second, a child with fever of recent onset generally warrants more immediate evaluation than does a child with FUO. The latter usually does not occur as an emergency and requires timely, but not urgent, diagnostic or therapeutic intervention. Third, although expectant antibiotic treatment of children with FUO generally is not indicated, expectant treatment of infants with FWS is recommended in most cases.

FEVER WITHOUT SOURCE

A convenient definition of FWS is the occurrence of fever for 1 week or less in a child in whom a careful history and physical examination fail to reveal a probable cause of the fever. An estimated 14 to 40 percent of children with fever have no localizing signs or symptoms.[9,13] Stein[93] found that the peak incidence occurs during the second year of life. On the basis of a review of private pediatric practices in upstate New York, Hoekelman and colleagues[46] predicted that every 4 to 5 days a practicing pediatrician would see one child between 1 and 24 months of age with FWS.

Most children with fever of recent onset have acute infectious diseases, the majority of which are self-limited.[108] A few of these patients have serious acute infectious diseases, including meningitis, bacteremia, and urinary tract infection, and a very few have acute noninfectious diseases or chronic disorders. For example, an occasional patient with FWS is discovered to have a disorder such as heat illness, drug poisoning, Kawasaki disease, malignancy, or connective tissue disease. However, these disorders occur infrequently. A physician faced with a child with FWS should consider the possibility of a noninfectious cause or the onset of a chronic disease, but unless a clinical clue suggests one of these entities, investigation in this direction is not warranted.

Many children with FWS are in the prodromal stages of an acute infectious illness, and evidence of a specific infection, such as pharyngitis, otitis media, or pneumonia, develops within hours to days of first being evaluated by a physician. Fever can precede the appearance of specific signs and symptoms by as long as 3 days, as in measles, Rocky Mountain spotted fever, and leptospirosis. In some infections, such as roseola, viral hepatitis, infectious mononucleosis, typhus, and typhoid fever, the interval between the onset of fever and the appearance of specific findings often is more than 3 days.

Occult Bacteremia

One major concern regarding a young child with FWS is the possibility that the child has occult bacteremia. The patient does not appear ill, is judged clinically well enough to be managed as an outpatient, and does not have an infection commonly associated with bacteremia, such as pneumonia, but the blood culture yields pathogenic bacteria such as *Streptococcus pneumoniae*, *Neisseria meningitidis*, *Haemophilus influenzae*, *Escherichia coli*, *Salmonella*, group A streptococcus, or *Staphylococcus aureus*. Before introduction of the pneumococcal conjugate vaccines, the incidence of occult bacteremia in children with FWS was approximately 3 to 5 percent.* More recent data report an incidence of less than 1 percent, although this figure may vary depending on vaccine coverage rates in the population studied.† A large prospective study of 3571 febrile children younger than 3 years of age found that no patients who had received at least 1 vaccination of heptavalent pneumococcal vaccine had

*References 7, 16, 26, 49, 60, 65, 74, 97, 108.
†References 2, 3, 32, 45, 84, 89, 95, 101, 106.

pneumococcal bacteremia.[27] With the introduction of the 13-valent pneumococcal conjugate vaccine, further decreases in occult bacteremia caused by pneumococci are anticipated.[28]

Historically, occult bacteremia has been found to occur more commonly in children with FWS than in febrile children of the same age with infections such as pharyngitis, otitis media, or upper respiratory tract infection. In the 1970s, investigators[65] reported the incidence of bacteremia in febrile children without an obvious source of infection to be 9.9 percent, as opposed to 3.3 percent in children with otitis media, upper respiratory tract infection, or a flulike syndrome. During the same era, Teele and colleagues[97] found a 3.9 percent incidence of bacteremia in children with FWS and a 1.5 percent incidence in comparably febrile children with otitis media or pharyngitis.

The risk for occult bacteremia developing in a child with FWS is age-related, with the greatest risk occurring in the first few months of life. Numerous studies have demonstrated a higher risk for bacteremia or other serious bacterial infections in febrile infants younger than 3 months old.[62,65,88,97] In a group of children with clinically unsuspected meningococcemia, all 12 patients who initially looked well enough to be treated as outpatients were younger than 24 months of age.[35] Bonadio and colleagues[22] found the incidence of positive bacterial cultures to be 12 percent in febrile infants younger than 4 weeks and 6 percent in those between 4 and 8 weeks of age.

The risk for having occult bacteremia and other serious bacterial infections increases with the severity of fever. In a prospective study of bacteremia in children seen in the outpatient department, McCarthy and colleagues[63] identified a small, but statistically significant, difference in the incidence of bacteremia between children with temperatures of 40° C (104° F) or higher and those with temperatures of 40.5° C (104.9° F) or higher. In a prospective study in which blood was obtained for culture from all febrile children younger than 2 years old seen in a walk-in clinic, no positive blood cultures were found in 44 children with FWS and rectal temperatures lower than 38.9° C (102° F), whereas five (3.9%) positive blood cultures were found in 129 children with FWS and rectal temperatures of 38.9° C (102° F) or higher.[86,97] Other studies have reported similar findings.[16,62,89] Several series of children with fevers of 41° C (105.8° F) or higher found a relatively high prevalence of bacteremia and other serious blood infections, especially meningitis and pneumonia.[21,62,86] However, even in this group of children with very high fever, most of those older than 2 or 3 months of age who looked well did not have a serious bacterial infection.

The white blood cell (WBC) count has been studied extensively as a potential tool in the diagnosis of occult bacteremia. On the basis of a study of hospitalized children, Todd[98] reported that the absolute number of polymorphonuclear leukocytes and the absolute number of nonsegmented polymorphonuclear leukocytes were more sensitive than was the total WBC count, the percentage of polymorphonuclear leukocytes, or the percentage of nonsegmented polymorphonuclear leukocytes. However, whether information based on hospitalized children—presumably all of whom had serious localized infections or looked ill enough to warrant hospitalization—can be applied to children with FWS who look well enough to be treated on an ambulatory basis is questionable.

Considerable debate continues over the usefulness of the WBC count in febrile children evaluated in the outpatient setting. McCarthy and associates[63] concluded that a WBC count of 15,000/mm^3 or greater was helpful in identifying patients at greatest risk for the development of bacteremia. Dershewitz[36] found a direct relationship between the total leukocyte count and the prevalence of bacteremia and stated that "knowledge of the count was a helpful but limited predictor of patients with positive blood cultures." Other investigators reported that the incidence of bacteremia increased with an increased WBC count[89] and that bacteremia most commonly occurred in patients with counts of 20,000/mm^3 or higher.[70]

Other studies have examined the utility of the WBC count specifically in children with FWS who look well enough to be treated on an outpatient basis. One such study found a sensitivity of 1.0 and a positive predictive value of 0.11 for a total WBC count of 15,000/mm^3.[97] Using a white blood cell count of 20,000/mm^3 would have decreased the sensitivity to 0.4 while increasing the positive predictive value to only 0.13. In another series, the sensitivity for a WBC count of 15,000/mm^3 was 0.87, with a specificity of 0.73.[16] Kline and coworkers[54] found that a WBC count of 15,000/mm^3 was more sensitive for *S. pneumoniae* bacteremia than for *H. influenzae* bacteremia. Although a total WBC count of 15,000/mm^3 does not accurately predict which child is or is not bacteremic, it is helpful in dividing the population of children with FWS into high- and low-risk groups.[17,45] However, the value of the 15,000/mm^3 level has been substantially reduced in the studies conducted since the pneumococcal conjugate vaccine was introduced.

Some investigators have found the erythrocyte sedimentation rate to be no more useful than the WBC count in predicting bacteremia in ambulatory febrile patients.[63] Others have reported that the serum concentration of C-reactive protein may be more accurate than the complete blood count or erythrocyte sedimentation rate in distinguishing bacterial from viral infections.[64,80] However, recent studies reported conflicting data regarding the utility of the C-reactive protein test in screening children 3 to 36 months old for occult bacteremia.[47,87] An elevated serum procalcitonin level has been found by some investigators to be at least as sensitive and specific as is C-reactive protein in predicting serious bacterial infection in children with fever and no localizing signs.[5,55,85]

Other hematologic findings that suggest bacteremia include thrombocytopenia,[31] Döhle inclusion bodies, toxic granulations, and vacuolization of neutrophils. In one study, peripheral blood smears of children younger than 24 months old with acute febrile illnesses were reviewed the following day by a single investigator to determine whether vacuolization and toxic granulations were present; when both abnormalities were present, the positive predictive value for bacteremia was 0.76.[57] The

presence of these findings should be considered when estimating the risk for bacteremia.[1,31,73]

Several studies have examined the response to acetaminophen and found no difference in the rate of reduction of temperature or improvement in clinical appearance between bacteremic and nonbacteremic children.[11,99,110] Mazur and associates,[61] however, found that febrile children aged 2 months to 6 years old who did not respond to a dose of acetaminophen by a reduction in temperature of at least 0.8° C in 2 hours had a statistically significant increased risk for having occult bacteremia in contrast to those who did respond.

The most important aspects of assessment of a febrile child are a careful history and physical examination. Laboratory data are secondary and should be ordered on the basis of the clinical assessment. By definition, a child with FWS has no localizing signs to explain the fever or indicate a site of infection. Many physicians suggest that a general impression can indicate whether the child has occult bacteremia. Some physicians have suggested that careful clinical judgment, based on extensive experience, can identify most, if not all, children with serious illnesses.[20,78] McCarthy and colleagues,[65-68] in a series of carefully designed studies, elucidated the variables of history and observation that were most useful in assessing febrile children. They found that observation of the variable *playfulness* had the strongest correlation with overall assessment.[67] However, they observed that even an experienced attending pediatrician could identify only 57 percent of seriously ill children by initial impression before performing a full physical examination. Dershewitz[36] found that private pediatricians were no more accurate than pediatric residents in identifying children with occult bacteremia and that in the private office, pediatricians were no better at predicting bacteremia in familiar patients than in first-time patients.

In a study of 292 consecutive febrile children seen in an emergency department, Waskerwitz and Berkelhammer[103] identified a subgroup of patients who had no localizing signs and who looked so well that they were predicted not to have bacteremia. The physicians were assisted in their assessment by a functional scale that gave 0 to 2 points for the child's eating, drinking, sleeping, and play activities, with a best possible score of 8. The group of patients who had functional scores of 5 or greater, with no localized infection and predicted clinically not to have bacteremia, were free of bacteremia, whereas 14 of 202 patients with functional scores of 4 or less were bacteremic. In this study, the physicians were not able to identify which patients had bacteremia and which did not; rather, they were able to identify one subgroup at high risk for having bacteremia and another at very low risk. Teach and Fleisher[96] found that although Yale Observation Scale scores were higher in patients with bacteremia than in those without, the difference was not clinically useful in detecting bacteremia in well-looking febrile children without a discernible focus of infection. The clinician's overall assessment of the degree of illness of the child appears to be a valuable, but not infallible, tool in estimating the risk for occult bacteremia in children with FWS.

Clinical Management of Fever Without Source

The clinician should not be dogmatic about the management of children with FWS. One reasonable approach, based on a careful history, thorough physical examination, and overall clinical impression, is to classify these children as being at low or high risk for the presence of occult bacteremia and other serious bacterial infections. For the low-risk group, no laboratory investigation is required routinely. For the high-risk group, a complete blood count and blood culture should be obtained, especially in young infants and children who are incompletely immunized. Many studies have shown that the most common serious bacterial infection in children with FWS is urinary tract infection.[4,101,104] Therefore, urinalysis and urine culture should be performed in febrile infants and children younger than 24 months of age. Lumbar puncture and chest radiography are considered on an individual basis. If the patient appears ill, admission to the hospital may be justified, even if all test results are negative. When high-risk children look well enough to be sent home, they are reasonable candidates for expectant antibiotic therapy, pending the outcome of blood and urine cultures. For patients clinically considered to be at moderate risk (not clearly high or low risk), the physician has the option of obtaining a WBC count and using the results to decide whether to obtain blood and urine for culture and prescribe antibiotics expectantly.

Table 63-1 lists risk factors for the development of occult bacteremia. Current information is not sufficient to warrant the use of scoring systems except as part of investigational series. In the final analysis, the clinician's judgment, taking into account all available clinical and laboratory data about each patient, is the guide to selecting which children require a diagnostic workup and expectant therapy with antibiotics.

If the physician elects to prescribe antibiotics while awaiting the results of blood culture, such antibiotic therapy should provide adequate coverage for *S. pneumoniae*, *N. meningitidis*, and *H. influenzae*, although the frequency of *H. influenzae* and *S. pneumoniae* has decreased dramatically with current immunization practice and *N. meningitidis* is uncommon. A single injection of ceftriaxone 50 to 75 mg/kg given while awaiting the results of blood culture has been successful in resolving fever, clearing bacteremia, and preventing meningitis and was found to be superior to oral regimens in several series.[14,18,41] Children with a positive blood culture should be recalled for reevaluation, even if they are afebrile.[8] Children who have been immunized against both *H. influenzae* and *S. pneumoniae* should be considered to be at relatively low risk for the development of occult bacteremia and may require less workup, unless they appear ill or have a very high fever.

Infants younger than 90 days old pose a special problem because they have an increased risk for developing a serious bacterial infection, clinical evaluation is more difficult, and a broader spectrum of invading organisms (e.g., group B streptococcus, *E. coli*, and *Listeria monocytogenes*) exists. Baker and coworkers[10] showed the safety of managing selected low-risk infants (i.e., normal WBC

TABLE 63-1 **Risk Factors for Occult Bacteremia**

Factor	High Risk	Low Risk
Age	≤3 mo	>3 mo
Immunization status*	Incomplete	Complete
Magnitude of fever	≥40° C (104° F)	≤39.4° C (103° F)
White blood cell count	≥15,000/mm^3	<15,000/mm^3
Peripheral blood smear	Toxic granulation or vacuolization of polymorphonuclear leukocytes, thrombocytopenia	Unremarkable
Underlying chronic disorder	Sickle-cell disease, immunodeficiency, malnutrition	None
History of contact with bacterial disease	Contact with *Neisseria meningitidis* or *Haemophilus influenzae*	None
Clinical appearance	Appears ill, toxic, or unhappy; inconsolable; irritable or lethargic; not eating or drinking enough	Looks well, playful, eating normally, not irritable

*Vaccination status is incomplete if the child has received fewer than 3 doses of *Haemophilus influenzae* vaccine and fewer than three doses of conjugated pneumococcal vaccine and is complete if the child received at least three doses of each vaccine.

count, urinalysis, lumbar puncture, and chest radiograph and, if diarrhea was present, negative smear for fecal leukocytes) 30 to 90 days of age on an outpatient basis without antibiotics. Jaskiewicz and coworkers[51] found the Rochester criteria (WBC count of 5000 to 15,000/mm^3, band count <1500/mm^3, spun urine specimen <10 WBCs/high-power field, stool specimen [if diarrhea] <5 WBCs/high-power field) to have a 98.9 percent negative predictive value in well-appearing, previously healthy infants younger than 90 days old with no focal infections. One reasonable practice guideline for managing infants with FWS is to hospitalize and treat all who appear toxic and all younger than 28 days. Those between 28 and 90 days of age can be managed as outpatients if they look well and the blood count, urinalysis, and cerebrospinal fluid analysis are within normal limits.[12,15]

FEVER OF UNKNOWN ORIGIN

The exact definition of FUO is a subject of considerable disagreement, and series in the pediatric literature differ in their criteria for inclusion. Brewis[23] defined FUO in children as a temperature of 38.3° C (101° F) or higher for 5 to 7 consecutive days without localizing signs or symptoms. In sharp contrast, McClung[69] and Lohr and Hendley[58] considered children with fever for at least 3 weeks on an outpatient basis or 1 week in the hospital to have FUO. Pizzo and associates,[83] however, required only that the fever be present for 2 weeks, with no distinction made between outpatient or in-hospital status. A reasonable working definition of FUO for clinical purposes is the presence of fever for 8 or more days in a child for whom a careful and thorough history, physical examination, and preliminary laboratory data fail to reveal a probable cause of the fever.

Most cases of FUO in children are caused by relatively common diseases.[39] In four series of FUO totaling 418 children, only 5 patients would be considered to have rare disorders (i.e., Behçet syndrome, ichthyosis, variant of "blue diaper" syndrome, diencephalic seizure disorder, and "possible chronic lead and/or arsenic intoxication").[23,58,69,83] The adage that FUO is more likely to be caused by an unusual manifestation of a common disorder than by a common manifestation of a rare disorder certainly is true in pediatrics. The three most common discernible causes of FUO in children, in order of decreasing frequency, are infectious diseases, connective tissue diseases, and neoplasms. In approximately 10 to 20 percent of cases, a definitive diagnosis never is established.

In the United States, the systemic infectious diseases diagnosed most frequently in children with FUO include tuberculosis, brucellosis, tularemia, salmonellosis, cat-scratch fever and infections caused by rickettsia, spirochetes (e.g., leptospirosis), Epstein-Barr virus, cytomegalic inclusion virus, human immunodeficiency virus (HIV), hepatitis viruses, and other viruses. The most common causes of localized infection are upper respiratory tract infections (e.g., sinusitis, otitis, tonsillitis), urinary tract infection, osteomyelitis, and occult abscesses, including hepatic and pelvic abscesses.

The connective tissue disease most commonly manifested as FUO in children is juvenile idiopathic arthritis, which accounts for more than 90 percent of connective tissue diseases in most series, followed by systemic lupus erythematosus, and then by undefined vasculitis.[58,69,72,83] Frequently, a definitive diagnosis of juvenile idiopathic arthritis can be made only after an extended period of observation because physical examination may yield few findings and the results of specific serologic studies generally are normal or negative.

Malignancy is a less frequent cause of FUO in children than in adults and usually is the third-largest group, after infectious diseases and connective tissue diseases. Malignancy accounted for 7 percent of FUO cases in the series reported by Pizzo and associates[83] and for 13 percent in the Lohr and Hendley[58] series. Leukemia and lymphoma are responsible for most cases of cancer manifested as FUO in children. Other tumors less commonly reported as causing FUO include neuroblastoma, hepatoma, sarcoma, and atrial myxoma.

The prognosis for children with FUO is better than that for adults, and most children with FUO have treatable or self-limited disease. Historically, mortality rates for children with FUO were 6 to 9 percent.[58,83] However, more contemporary studies indicate that mortality is quite low.[79]

Diagnostic Approach to a Child with Fever of Unknown Origin

A child with FUO is admitted to the hospital for more than simply laboratory investigation. Hospitalization provides an opportunity to observe the child, repeat the history and physical examination, analyze all available data, and investigate every potential diagnostic lead. In the Lohr and Hendley[58] series of 54 children with FUO, an incomplete history delayed establishing the diagnosis in 9 cases, and physical findings that were ignored delayed rendering the diagnosis in 4 cases. In McClung's report[69] of 99 pediatric cases of FUO, errors in the history or physical examination obscured the correct diagnosis for at least 10 patients. Failure to use existing laboratory data correctly is another common factor preventing early determination of the diagnosis in children with FUO.[58,83]

Clinical Evaluation

The first and most important step in the diagnostic workup of a child with FUO is obtaining a complete and detailed history and conducting a physical examination. The clinical evaluation must be thorough and careful, and it must be repeated frequently. Often, a patient or parent eventually recalls information that was omitted or forgotten when the initial history was obtained. Physical findings change, and abnormalities not originally present can appear subsequently. Lohr and Hendley[58] noted that in more than 25 percent of children admitted to the hospital with FUO, significant physical findings developed that were not present at the time of admission.

A detailed history should be obtained regarding contact with infected or otherwise ill persons and any exposure to animals, including pets and wild animals. The number of children with zoonotic infections is increasing each year. History of a cat scratch or exposure to kittens may be a clue for *Bartonella henselae*. Immunization of domestic animals such as the dog against leptospirosis can prevent canine disease, but it does not prevent carriage, excretion, and transmission of this infection. A history of travel extending back to birth must be elicited. Reemergence of histoplasmosis, coccidioidomycosis, blastomycosis, leishmaniasis, or malaria years after visiting or living in an endemic area can occur. Inquiring about prophylactic immunizations, precautions taken against the ingestion of contaminated food or water, and malarial prophylaxis is important. Questioning should include the possibility that rocks, soil, or artifacts from geographically distant regions may have been brought into the home, as well as the possibility that contact with persons who have visited distant countries has occurred. Even contact with insects can be important. Tick bites can be a clue to Rocky Mountain spotted fever or tick-borne relapsing fever. North American mosquitoes and some ticks carry a variety of arboviruses.

The physician should determine whether the patient has eaten game meat, raw meat, or raw shellfish. A history of pica should be sought routinely. Ingestion of dirt can suggest a diagnosis of visceral larva migrans, toxoplasmosis, or other infectious diseases. A detailed history regarding all medications, including topical agents and nonprescription items, must be elicited carefully. Any history of surgical procedures should be explored.

Questions designed to determine the genetic or ethnic background of the patient can reveal information that specifically suggests or largely excludes diagnoses such as nephrogenic diabetes insipidus (found in Ulster Scots), familial Mediterranean fever (found in Armenians, Arabs, and Sephardic Jews), familial dysautonomia (found in Jews), and Kikuchi-Fujimoto disease, a benign and self-limited histiocytic necrotizing lymphadenitis (found mostly in young Asian females and characterized by fever, lymphadenopathy, and malaise).

The history should be exacting regarding the duration, height, and pattern of the fever, as well as the circumstances under which temperature elevation occurs, whether the child appears ill or any signs or symptoms develop, and how well the fever responds to antipyretic drugs. A history of "fever" occurring only after exercise or late in the afternoon can indicate parental concern about normal variations in body temperature. A history of high fever occurring in the absence of malaise or other generalized signs can be a clue to factitious fever. The physician also should obtain a careful history regarding how well the fever has been documented. Has a thermometer been used, by whom, and in whose presence? A history of sweating and heat intolerance can indicate hyperthyroidism, whereas a history of heat intolerance with the absence of sweating can be a clue to ectodermal dysplasia.

Several investigators found that neither the pattern of fever nor its duration was useful in pointing to or establishing a diagnosis in children with FUO.[58,83] However, occasionally the character of the fever can be helpful. *Intermittent fever* is characterized by a return of temperature to normal at least once daily. If the peak of fever is high and the rate of defervescence quick, this pattern often is referred to as *hectic* or *spiking*. Intermittent fevers suggest pyogenic infections but also occur with tuberculosis, lymphoma, and juvenile idiopathic arthritis. In *remittent fever*, the temperature fluctuates but does not return to normal. A *sustained fever* pattern is characterized by persistent fever with little or no fluctuation and can occur in typhoid fever or typhus. Antipyretic agents can make a remittent or sustained fever appear intermittent. *Relapsing fever* refers to a pattern in which the patient is afebrile for 1 or more days between episodes of fever and can be seen with malaria, rat-bite fever, infection with *Borrelia*, and lymphoma. Recurrent episodes of fever of more than a year's duration can suggest metabolic defects, central nervous system abnormalities in temperature control, and immunodeficient states.

The general activity and appearance of the patient should be observed, vital signs checked, and growth parameters measured. Weight loss is an important, though nonspecific, finding. Impairment of linear growth or short stature can be a clue to inflammatory bowel disease, an intracranial lesion involving the pituitary gland, or a long-standing chronic disease. Examining the patient during an episode of fever to observe the presence or absence of sweating, the effect of the fever on the heart and respiratory rate, the presence or absence of malaise

or other symptoms, and the appearance of "toxicity" is helpful. The rash of juvenile idiopathic arthritis characteristically is evanescent and may be present only during periods of temperature elevation.

Some special aspects of the physical examination merit mention. Hypohidrosis, anomalous dentition, and sparse hair, particularly involving the eyebrows and eyelashes, suggest anhidrotic ectodermal dysplasia. Palpebral conjunctivitis can be a clue to the presence of infectious mononucleosis, Newcastle disease, or lupus erythematosus, whereas predominantly bulbar conjunctivitis can suggest leptospirosis or Kawasaki disease. Phlyctenular conjunctivitis can signal tuberculosis.

Absence of the pupillary constrictor response can be caused by a deficiency of the constrictor sphincter muscle of the eye. This muscle, derived from ectoderm rather than mesoderm, develops embryologically at the same time that hypothalamic structures and function are undergoing differentiation. Absence of this muscle can suggest that the elevation in temperature is the result of hypothalamic or autonomic dysfunction. Careful funduscopic examination can disclose evidence of miliary tuberculosis, vasculitis, or toxoplasmosis. Lack of tears, absence of corneal reflexes, and a smooth tongue with absence of the fungiform papillae suggest familial dysautonomia.

Purulent or persistent nasal discharge can be a sign of sinusitis. The physician should palpate for tenderness over the sinuses.

Hyperemia of the pharynx, even in the absence of exudate or specific symptoms, can be a clue to the diagnosis of infectious mononucleosis, cytomegalic inclusion disease, toxoplasmosis, tularemia, or leptospirosis. Gingival hypertrophy or inflammation and loosening or loss of teeth can indicate leukemia or Langerhans cell histiocytosis.

The bones and muscles should be palpated carefully. Tenderness over a bone can be found in cases of osteomyelitis or marrow invasion by neoplastic disease. The appreciation of a new heart murmur may result from infective endocarditis. Muscle tenderness can be associated with trichinosis, dermatomyositis, polyarteritis, or various arboviral infections.

The search for skin lesions and rash must be careful, extensive, and repeated. Petechiae can indicate endocarditis or other sources of bacteremia but also can occur with viral and rickettsial infections. A seborrheic rash can be a sign of histiocytosis. A small papule present for over a week may be the inoculation site for cat-scratch disease.

A careful rectal examination can reveal pararectal tenderness or a mass indicative of a pelvic abscess or tumor. A test for occult blood should be performed on stool. Examination of the external genitalia should be completed on patients of all ages, and sexually active adolescent females should undergo a pelvic examination.

Laboratory Evaluation

The extent of laboratory investigation depends on the age of the patient, duration of the fever, and history and physical examination findings. Laboratory studies should be directed, as much as possible, toward the most likely diagnostic possibilities. The tempo of the diagnostic evaluation should be adjusted to the severity of the illness. In a critically ill child, speedy evaluation is important. If the patient is less severely ill, however, the evaluation can proceed more slowly; sometimes the fever can disappear without apparent explanation before a definitive diagnosis can be established and any invasive diagnostic procedures have been undertaken.

A complete blood count and careful examination of the peripheral smear are indicated for all patients. Anemia, thrombocytosis, and thrombocytopenia should be noted. Although mild or moderate changes in the total WBC or differential count usually are of no help, in some series, children with more than 10,000 polymorphonuclear leukocytes or 500 nonsegmented neutrophils/mm^3 were found to have a greater likelihood of having a serious bacterial infection.[93,98] Atypical lymphocytes generally indicate viral infection, whereas bizarre or immature forms can suggest leukemia. Although the erythrocyte sedimentation rate and C-reactive protein are of no specific diagnostic value, they are a general indicator of inflammation and can help in ruling out factitious fever, determining the need for further evaluation, and monitoring the progress of the disease process.

Blood should be obtained from all patients for aerobic and anaerobic culture. In select cases, media appropriate for the isolation of *Francisella* organisms, *Leptospira*, and *Spirillum* also should be used.

Urine analysis and culture should be completed for all patients. In one series of FUO in children, failure to perform urinalysis and failure to investigate pyuria adequately were the most common laboratory errors.[69] Radiographic study of the urinary tract, however, should be performed only when indicated.

All patients should undergo radiographic examination of the chest. Diagnostic imaging of the nasal sinuses, mastoids, and gastrointestinal tract is performed initially only for specific indications but should be done eventually in all children whose fever persists without explanation for a long period. Persistent fever and elevation of the erythrocyte sedimentation rate or C-reactive protein, with or without anemia, abdominal complaints, anorexia, and weight loss, are sufficient indications for radiographic study to rule out inflammatory bowel disease.

All patients should have an intradermal tuberculin skin test. Control skin tests with antigens such as *Candida* are of limited value because the anergy may be specific for tuberculosis rather than universal for all skin-testing materials.[59,71,75,76] A positive control test result and negative tuberculin test result do not rule out tuberculosis.

Bone marrow examination is most useful in diagnosing cancer (especially leukemia), histiocytic disorders, and hemophagocytic disease. It is less useful in determining infection. Hayani and associates[44] reviewed the results of 414 bone marrow examinations for FUO in children. In only one case was an organism (*Salmonella* group D) recovered from the marrow that also was not recovered from blood or another source. Noninfectious causes of FUO were found in 8 percent of specimens: malignancy (6.7%), hemophagocytic lymphohistiocytosis (0.7%), histiocytosis (0.5%), and hypoplastic anemia (0.2%). In

most of these cases, the diagnosis had been suspected clinically before the bone marrow was examined.

Patients should undergo a serum test for HIV infection. Other appropriate serologic tests can help establish a diagnosis of cat-scratch disease, brucellosis, tularemia, Epstein-Barr virus infection, cytomegalovirus infection, other viral infections, toxoplasmosis, and certain fungal infections.

Hepatic enzymes and serum chemistry, including electrolytes, urea nitrogen, and creatinine, should be determined in all patients. Serum antinuclear antibody should be measured in those older than 5 years if family history is significant or clinical suspicion warrants it. Serum hepatitis antigens, electrocardiography, electroencephalography, echocardiography, and stool culture and examination for ova and parasites generally should be performed in selected cases. Other tests to be considered for individual patients include ophthalmologic examination by slit lamp, radiographic bone survey, technetium bone scan, abdominal imaging by ultrasonography, computed tomography (CT), or magnetic resonance imaging (MRI).[25,82] CT scanning and indium-111 scanning[40] can detect inflammatory lesions and tumors. Such scanning procedures offer a relatively noninvasive technique for screening patients with FUO for a variety of disorders. Although Steele and associates[92] found that radionucleotide scans seldom led to unsuspected diagnoses in children and suggested that they not be used indiscriminately, gallium scanning has been helpful in diagnosing adult patients with FUO,[43] but is not generally recommended in children. Lymph node biopsy, liver biopsy, and exploratory laparoscopy are reserved for patients with evidence of involvement of these organs.

In general, antibiotics or other medications should not be administered empirically as a diagnostic measure in children with FUO. Exceptions include the use of nonsteroidal agents in children with presumed juvenile idiopathic arthritis and the use of antituberculosis drugs in critically ill children thought to have disseminated tuberculosis. Empirical trials of broad-spectrum antibiotics generally do more to obscure than illuminate the etiology of FUO and can mask or delay establishing the diagnosis of infections such as meningitis, parameningeal infection, endocarditis, or osteomyelitis.

Examples of disorders that can be manifested as FUO in children are listed in Table 63-2. A few of these disorders are discussed briefly in the following sections.

TABLE 63-2 **Causes of Fever of Unknown Origin in Children**

Infectious Diseases

Bacterial
Bacterial endocarditis
Brucellosis
Cat-scratch disease
Leptospirosis
Liver abscess
Mastoiditis (chronic)
Osteomyelitis
Pelvic abscess
Perinephric abscess
Pyelonephritis
Salmonellosis
Sinusitis
Subdiaphragmatic abscess
Tuberculosis
Tularemia

Viral
Adenovirus
Arboviruses
Cytomegalovirus
Epstein-Barr virus (infectious mononucleosis)
Hepatitis viruses

Chlamydial
Lymphogranuloma venereum
Psittacosis

Rickettsial
Q fever
Rocky Mountain spotted fever

Fungal
Blastomycosis (nonpulmonary)
Histoplasmosis (disseminated)

Parasitic
Malaria
Toxoplasmosis
Visceral larva migrans

Unclassified
Sarcoidosis

Collagen Vascular Diseases
Juvenile rheumatoid arthritis
Polyarteritis nodosa
Systemic lupus erythematosus

Malignancies
Hodgkin disease
Leukemia and lymphoma
Neuroblastoma

Miscellaneous
Central diabetes insipidus
Drug fever
Ectodermal dysplasia
Factitious fever
Familial dysautonomia
Granulomatous colitis
Hemophagocytic lymphohistiocytosis
Infantile cortical hyperostosis
Kikuchi-Fujimoto disease
Nephrogenic diabetes insipidus
Pancreatitis
Periodic fever
Serum sickness
Thyrotoxicosis
Ulcerative colitis

Infectious Causes of Fever of Unknown Origin

Infectious causes of FUO can be divided into systemic and localized. Immunodeficient states may be considered under the general classification of infections.

Generalized Infections

Brucellosis. The manifestation of this disease as FUO is explained by the nonspecific symptoms that it engenders and by the chronicity of untreated infection. Many physicians, particularly in urban areas, tend to ignore the possibility of this disease and neglect to inquire about a history of exposure to animals or animal products, especially the consumption of unpasteurized goat's milk cheese (see Chapter 128).

Cat-Scratch Disease. During recent years, many children with FUO have proved to be infected with *B. henselae*. Cat-scratch disease is one of the most common causes of FUO in patients seen at the infectious disease service at Texas Children's Hospital in Houston.[6] Most of the children with this manifestation of cat-scratch disease have hepatosplenic involvement. Jacobs and Schutze[48] reported that *B. henselae* infection was the cause of 4.8 percent of all cases of FUO at the Arkansas Children's Hospital and 10.9 percent of the cases of FUO caused by infection. *B. henselae* infection is best diagnosed by serologic evaluation (i.e., immunofluorescence assay that detects serum antibody to *B. henselae*). Biopsy of lesions (e.g., lymph nodes, liver, bone marrow) may allow visualization of bacilli with the Warthin-Starry silver stain; however, this finding is not specific for *B. henselae*. Management of patients with cat-scratch disease is primarily symptomatic because the disease usually is self-limited. Antimicrobial therapy can be helpful in acutely or severely ill patients, especially those with hepatosplenic disease. Several oral antimicrobial regimens (rifampin, trimethoprim-sulfamethoxazole, and azithromycin) and parenteral gentamicin have been used successfully for the treatment of this disease. Specifically, rifampin 20 mg/kg/day in two divided doses for 14 days has been particularly efficacious.[6] However, the optimal duration of therapy is not known.

Leptospirosis. Leptospirosis is caused by a single family of organisms composed of multiple serotypes; it is one of the most widespread zoonoses in the world. Transmission of infection from animal to human can occur by direct contact with the blood, tissue, organs, or urine of infected animals or indirectly by exposure to an environment that has been contaminated by leptospires. The organism also can be acquired from soil or from fresh water after ingestion. Reports indicate that leptospirosis is not a rare disease, that many infections are not associated with occupational exposure, and that urban and suburban cases are becoming more prevalent.[111] Clinical manifestations of leptospirosis usually are not specific. A variety of laboratory aids are available, but specimens must be collected and handled properly. In some cases, establishing a definitive diagnosis may be impossible; negative cultures or failure to demonstrate a rise in antibody titer does not exclude the possibility that the patient has active infection because the organism may not be present in the specimens that have been cultured, the antibody titer may have peaked before an acute-phase specimen was collected, and antibiotic therapy may suppress the development of positive titers or delay their appearance (see Chapter 141).

Toxoplasmosis. Toxoplasmosis should be considered in any child with persistent fever. Cervical or supraclavicular adenopathy is present in most cases, but occasionally fever is the only manifestation. The diagnosis is established by demonstration of a rising serologic titer; antibody to *Toxoplasma gondii* is so prevalent that demonstration of a high titer alone is not diagnostic of acute infection. Demonstration of *Toxoplasma* in tissue sections or body fluid is highly suggestive, although the organism can persist in tissue for years. Isolation of the parasite is not absolutely diagnostic of recent infection (see Chapter 223).

Malaria. Malaria also should be considered in children with FUO. In addition to fever, splenomegaly usually is present. A history of travel to endemic areas should be sought, although malaria has occurred in patients who never traveled outside the United States. Disease can occur even in persons who have taken antimalarial drugs when they visited the endemic region. A delay of several months can occur between the development of infection and the onset of symptoms. The infection can be transmitted from a person who has visited an endemic area to one who has not when an appropriate mosquito vector is present. Malaria also can be acquired by blood transfusion or by the use of needles and syringes contaminated by the parasite. Demonstration of malarial organisms on appropriately stained thin or thick smears of blood is diagnostic (see Chapter 219).

Salmonellosis. *Salmonella* organisms are contaminants in many food products. In view of the nonspecific signs and symptoms with which salmonellosis can occur, its association with FUO in children is not surprising. Repetitive blood and stool cultures are most helpful in establishing a diagnosis (see Chapter 111).

Tuberculosis. Tuberculosis is an important cause of FUO in children, as well as in adults. Nonpulmonary tuberculosis is manifested as FUO more frequently than is pulmonary tuberculosis, which usually is evident on routine chest radiographs. FUO occurs most commonly with disseminated tuberculosis or infection of the liver, peritoneum, pericardium, or genitourinary tract. Active disseminated tuberculosis has been well documented in children with negative results on chest radiography and tuberculin skin tests.[76,94] Negative interferon-γ release assay results also may occur.[33] A high index of suspicion and a careful history of possible contacts are important to make the diagnosis. Funduscopic examination can reveal choroid tubercles. Liver and bone marrow

frequently are involved in children with miliary tuberculosis; liver biopsy specimens and bone marrow aspirates should be obtained and processed for morphologic evaluation and culture. If the chest radiograph yields abnormal results, cultures of gastric aspirates, sputum, or both should be obtained. Because nontuberculous mycobacteria (i.e., atypical organisms) are present in the gastric contents of normal individuals, demonstration of acid-fast organisms on smears of gastric secretion does not necessarily indicate disease. Rarely, a patient with tuberculous pericarditis has fever, weight loss, and weakness but no precordial pain or other specific cardiac complaints. Disseminated infection with atypical mycobacteria generally is seen in patients infected with HIV (see Chapter 96) or those with other immunodeficiencies.

Tularemia. Generally, failure to consider tularemia in children with FUO may be attributed to a lack of appreciation of the many sources of infection and the various routes of inoculation. The organism can be acquired from contact with a variety of animal species, as well as from ticks, mosquitoes, lice, fleas, flies, and contaminated water. The organism can penetrate mucous membranes and broken or unbroken skin, or it can be inhaled or swallowed. Patients and parents should be questioned about animal contact and the ingestion of rabbit or squirrel meat (see Chapter 132).

Viral Infections. Infection by most viruses produces an illness that is relatively brief. Exceptions to this rule can include infections by adenovirus, cytomegalovirus, Epstein-Barr virus, hepatitis viruses, and certain arboviruses. In all of these diseases, symptoms are extremely variable and signs and symptoms frequently are nonspecific. The diagnosis can be established by appropriate cultures and serologic studies (see Chapter 252).

Immunodeficiency. A variety of congenital and acquired immunodeficiency states can be manifested as FUO. Patients with immunoglobulin deficiencies (e.g., Bruton agammaglobulinemia) may have a long history of recurrent fever, with or without evident infection, whereas patients with abnormalities in lymphocyte function are more likely to have prolonged fever caused by persistent viral or parasitic infection.

Localized Infections

Bacterial Endocarditis. Infective endocarditis is an infrequent cause of FUO in children. Acute bacterial endocarditis tends to be fulminant, but the subacute form begins insidiously, generally at the site of a preexisting cardiac lesion. Subacute bacterial endocarditis is a rare occurrence in infants and increases in frequency with advancing age. The organisms most commonly encountered are viridans streptococci, enterococci, *S. aureus*, and *Staphylococcus epidermidis*. The absence of a cardiac murmur does not exclude the possibility of endocarditis, especially when the infection is limited to the right side of the heart. Endocarditis also can occur in the absence of positive blood cultures, particularly in association with the following factors: use of antibiotics for an undefined febrile illness, right-sided cardiac lesions, prolonged duration of disease, infection by unusual organisms such as *Brucella* or *Coxiella burnetii*, and inadequate culture methods for the detection of infection with anaerobic organisms. Frequently associated laboratory findings include anemia, leukocytosis, and an elevated erythrocyte sedimentation rate. Several blood cultures (aerobic and anaerobic) of adequate volume should be obtained before starting antibiotics. Echocardiography can reveal vegetations, but negative results do not rule out endocarditis (see Chapter 26).

Bone and Joint Infections. Infections of bones and joints usually can be diagnosed clinically but occasionally are manifested as FUO. This manifestation occurs commonly in young children who cannot explain where they hurt and is more likely to occur with osteomyelitis than with septic arthritis. Infection of the pelvic bones is implicated most often in this regard. Radioisotopic bone scan and MRI are more sensitive than are plain radiographs of the bones (see Chapters 55 and 56).

Intra-Abdominal Abscesses. Subphrenic, perinephric, and pelvic abscesses may be manifested as FUO. A history of previous intra-abdominal disease or abdominal surgery or a history of vague abdominal complaints should heighten suspicion of an intra-abdominal collection of pus. The organisms involved most commonly are *S. aureus*, streptococci, *E. coli*, and anaerobic flora. Fever may be the only sign of a pelvic, perinephric, or psoas abscess. Urinalysis generally yields normal results, but the mass can be demonstrated by ultrasound examination, CT, or MRI.

Liver Abscess and Other Hepatic Infections. Pyogenic liver abscesses are encountered most frequently in immunocompromised pediatric patients but can be seen in otherwise normal children.[53] In some patients, persistent fever is the only finding. Blood cultures usually are sterile, and serum levels of liver enzymes generally are close to or within normal limits. Many patients have hepatomegaly and right upper quadrant abdominal tenderness. The diagnosis can be established by examination of the liver by ultrasonography, radioisotope scanning, CT, or MRI. Bacterial hepatitis and bacterial cholangitis can occur in the absence of jaundice and other specific signs of liver dysfunction.[105,109] Granulomatous hepatitis is not a specific disease but rather a syndrome characterized by granuloma formation within the liver. A specific cause cannot be determined in every case. Although most reported cases have been in adults,[90] pediatric cases do occur, particularly with Epstein-Barr virus infection and with cat-scratch disease. The diagnosis can be made by ultrasound or other diagnostic imaging (see Chapter 49).

Upper Respiratory Tract Infections. Frequently, infections of the upper respiratory tract and related organs are manifested as FUO.[58,69,83] Although obvious signs or symptoms would be expected, the complaints

often appear trivial and may be ignored. Reported cases of FUO have occurred in children with mastoiditis, sinusitis, chronic or recurrent otitis media, chronic or recurrent pharyngitis, tonsillitis, peritonsillar abscess, and nonspecific upper respiratory tract infection. A parapharyngeal inflammatory pseudotumor manifested as FUO has been reported in a 3-year-old girl in whom anemia and weight loss also developed. The cause never was discerned, but the symptoms resolved after surgical removal of the inflammatory mass.[29]

Noninfectious Causes of Fever of Unknown Origin

Central Nervous System Dysfunction

Children with severe brain damage can have dysfunctional thermoregulation, and body temperature in some of these patients can remain elevated for months. Cases of otherwise neurologically normal children who have had fever as a result of central dysfunction also have been reported. Berger[19] discussed a 16-year-old child with recurrent episodes of fever that were thought to represent a form of epilepsy but disappeared when treatment with phenytoin was begun. Wolff and associates[107] reported a 14-year-old child with cyclic episodes of fever, nausea, vomiting, and emotional disturbance caused by a central nervous system lesion.

Diabetes Insipidus

Central and nephrogenic diabetes insipidus can cause FUO in infants and young children. Polyuria and polydipsia may not be appreciated during infancy. Hyperthermia, weight loss, and peripheral vascular collapse can ensue. Signs of dehydration or an increased serum concentration of sodium suggests the diagnosis. The diagnosis is established by simultaneous measurements of urine and serum electrolytes and osmolality during periods of normal hydration and after carefully controlled periods of water deprivation. Serum levels of antidiuretic hormone also can be measured by radioimmunoassay.

Drug Fever

Nearly any medication can be associated with an allergic reaction, including fever. The offending agent may be a prescribed drug, an over-the-counter preparation, or a street drug such as amphetamine or 1-[1-phenylcyclohexyl] piperidine (phencyclidine [PCP]). Atropine, whether taken systemically or used topically in the form of eye drops, can cause elevation of temperature. Phenothiazines and anticholinergic drugs can inhibit sweating and impair regulation of temperature. Epinephrine and related compounds can affect thermoregulatory control mechanisms and produce fever. Drug fever can be low-grade or high and spiking. Fever can be continuous or intermittent. Discontinuation of the drug generally is followed by disappearance of the fever within 48 to 72 hours, but it sometimes persists for as long as a month as a result of slow excretion of the offending agent.

Factitious Fever

A parent or patient may report the presence of fever that does not exist. The reading of the thermometer can be increased by immersing the bulb in hot liquid or by rinsing the mouth with hot liquid immediately before inserting the thermometer. Clues to factitious fever include absence of tachycardia, malaise, or discomfort despite a markedly elevated temperature; apparent rapid defervescence unaccompanied by diaphoresis; failure of the temperature curve to follow the normal diurnal variation of body temperature; hyperpyrexia; and normal temperature reading when the temperature is obtained rectally by someone who remains in attendance during the procedure. The presence of fever also can be confirmed or excluded by measuring the temperature of a freshly voided urine specimen. The current use of electronic thermometers in most hospitals decreases the possibility of factitious fever in that setting because the nurse or aide usually brings in the thermometer and stays in attendance during the relatively brief period of insertion. In more unusual cases, the patient or parent can induce fever by the injection of infective or foreign materials.

Familial Dysautonomia

Familial dysautonomia (Riley-Day syndrome), an autosomal recessive disorder, is characterized by autonomic and peripheral sensory nerve dysfunction. Eighty percent of patients are children of Jewish parentage, particularly Ashkenazi Jews. Defective regulation of temperature can result in hypothermia or hyperthermia.[34]

A careful history and physical examination can reveal poorly coordinated swallowing movements that lead to recurrent aspiration and pneumonia; recurrent episodes of vomiting; excessive salivation; excessive or diminished sweating; diminished formation of tears; periods of hypotension, hypertension, or both; and erythema or blanching of the skin. The fungiform papillae of the tongue are absent or diminished in number, and the sensation of taste is deficient.[91] Self-mutilation or multiple sites of skin trauma can reflect diminished or absent pain sensation peripherally. Deep tendon reflexes are diminished; corneal reflexes are impaired; and mental deficiency, dysarthria, and emotional lability are common findings.

Excretion of vanillylmandelic acid in urine can be diminished, and excretion of homovanillic acid can be increased. Administration of histamine intradermally can produce a wheal but no flare or pain at the site of injection. Placement of methacholine (2.5%) into the conjunctival sac produces pupillary constriction in children with familial dysautonomia but no response in normal children. Intravenous infusion of norepinephrine is followed by an exaggerated pressor response, and the hypotensive response to infusion of methacholine is increased.

Hemophagocytic Lymphohistiocytosis

Hemophagocytic lymphohistiocytosis is characterized by prolonged fever, hepatosplenomegaly, cytopenia, and

hyperferritinemia and hemophagocytosis in the bone marrow, liver, spleen, or lymph nodes.[50,77] It is a life-threatening and unusual disorder in which uncontrolled proliferation of activated lymphocytes and histiocytes results in unregulated hypersecretion of inflammatory cytokines. Hemophagocytic lymphohistiocytosis can be primarily a familial disease or can be manifested as a reactive process triggered by infection, malignancy, immunologic disease, or drugs.

The diagnosis of hemophagocytic lymphohistiocytosis is suggested by fever, hepatosplenomegaly, cytopenia in at least two cell lines, hypertriglyceridemia or hypofibrinogenemia, and an elevated ferritin level. Other laboratory abnormalities associated with hemophagocytic lymphohistiocytosis can include low or absent natural killer cell activity or elevated soluble CD25 (α chain of the interleukin-2 receptor), but these studies take time for results to return from reference laboratories.[52] Because this disorder can be manifested initially as FUO and progress to masquerade as overwhelming sepsis, a high index of suspicion is required for establishing the diagnosis. Further investigation should include evaluation of bone marrow or lymph nodes for the presence of hemophagocytosis. Therapy should include treatment of the underlying infection or trigger, if one exists, in addition to appropriate immune modulation therapies. A substantial proportion of hemophagocytic lymphohistiocytosis cases progress rapidly to death despite administration of appropriate chemotherapy.[50,52,77]

Inflammatory Bowel Disease

Fever is a prominent feature in many children with inflammatory bowel disease.[30,56,102] A greater percentage of children than adults with regional enteritis have fever. Appropriate contrast-enhanced radiographic studies of the intestines should be undertaken in children with prolonged FUO, even in the absence of findings specifically referable to the gastrointestinal tract, especially if the erythrocyte sedimentation rate is elevated and if the patient has anemia, weight loss, failure of linear growth, or a positive stool guaiac test.

Ulcerative colitis can be manifested as FUO, though less commonly than with regional enteritis. In patients with ulcerative colitis, symptoms referable to the gastrointestinal tract generally are present at the time that the patient is febrile.

Infantile Cortical Hyperostosis

The cause of infantile cortical hyperostosis (i.e., Caffey disease) is unknown. The decreased incidence in recent years suggests an infectious, possibly a viral, cause. Spontaneous hyperplasia of subperiosteal bone begins during infancy and is associated with swelling of the overlying tissues. The skull, mandible, clavicles, scapula, and ribs are affected most frequently, but in some children the long bones and even the metatarsal bones can be involved. Most patients have persistent fever, sometimes as high as 40° C (104° F). Tenderness over the affected regions, irritability, elevated erythrocyte sedimentation rate, and leukocytosis are common findings. The diagnosis is established by the clinical picture in conjunction with radiographically demonstrated periosteal involvement.

Juvenile Idiopathic (Rheumatoid) Arthritis

Juvenile idiopathic arthritis is a chronic inflammatory disorder that usually is manifested as one of three distinct syndromes: the systemic form, characterized by high, spiking temperatures (generally once or twice each day), evanescent rash, and lymphadenopathy; a polyarticular form; and a monarticular or pauciarticular form. Fever is associated with all three manifestations but occurs most commonly in the systemic form, in which case it is present in nearly 100 percent of patients. This form also is the one most likely to be manifested as FUO.[24] Arthritis may not develop for months to years after onset of the fever. The diagnosis often needs to be made by exclusion because no laboratory findings are specific for the diagnosis.

Periodic Fevers

The periodic fever disorders, also known as unprovoked inflammatory events that sometimes can occur without accompanying fever, are rare heritable disorders characterized by recurrent (periodic or irregular) attacks of fever and inflammation.[100] Between attacks, patients feel well. These disorders include familial Mediterranean fever and hyperimmunoglobulinemia D with periodic fever syndrome, which are autosomal recessive diseases. Familial Mediterranean fever is the most common periodic fever syndrome and is caused by a mutation in the *MEFV* gene, which encodes the protein pyrin. The illness is characterized by fever for 1 to 3 days accompanied by abdominal pain, pleurisy, and arthritis or arthralgia. Laboratory findings include peripheral leukocytosis and elevation of acute-phase reactants. The episodes occur irregularly. Persistent inflammation can lead to secondary amyloidosis. The disease occurs most commonly in Armenians, North Africans, Sephardic Jews, and Turks and sometimes Ashkenazi Jews, Italians, and Greeks or persons of other ethnicities. Hyperimmunoglobulinemia D with periodic fever syndrome is associated with mutations in the *MVK* gene that encodes mevalonate kinase. Disease commonly presents before the age of 1 year, with episodes of fever lasting 3 to 7 days accompanied by cervical lymphadenopathy, abdominal pain, and vomiting or diarrhea.[37,42] Patients also can have aphthous ulcers, rash, splenomegaly, and arthritis or arthralgias. Attacks may occur at irregular intervals and can be triggered by stress, vaccination, and viral infections. Immunoglobulin (Ig) D levels are elevated, and most patients also have elevated IgA. Secondary amyloidosis is rare.

Other periodic fever syndromes include tumor necrosis factor receptor–associated periodic syndrome; pyogenic sterile arthritis, pyoderma gangrenosum syndrome, and acne; and Blau syndrome. These are rare disorders that are autosomal dominant in transmission. The genes associated with these disorders encode proteins that share domains involved in innate immunity and apoptosis. Muckle-Wells syndrome, familial cold autoinflammatory syndrome, and neonatal-onset multisystem inflammatory

disorder are cryopyrin-associated periodic syndromes, a group of overlapping autoinflammatory disorders in which fever is an accompanying but not major feature of illness.

The syndrome of periodic fever with aphthous stomatitis, pharyngitis, and adenitis is a relatively common periodic fever syndrome. Symptoms such as fever, pharyngitis, cervical lymphadenopathy, and mild aphthous ulcers usually recur at 3- to 4-week intervals, generally beginning abruptly and resolving spontaneously in 3 to 5 days. Leukocytosis and elevation of inflammatory markers occur during the acute episode and normalize in between. The cause of this syndrome remains unknown.[38]

CHAPTER 64

Toxic Shock Syndrome

Jeffrey Suen

Illnesses resembling toxic shock syndrome (TSS) have been reported since 1927,[7,102,115,295,318] but the initial description of TSS as a disease was published in 1978 by Dr. James K. Todd and colleagues.[305] The clinical illness is defined by criteria formulated for epidemiologic studies (Table 64-1). TSS has unique clinical manifestations not generally noted in septic shock, including diffuse erythroderma, delayed desquamation of the palms and soles, conjunctival and pharyngeal hyperemia, muscle injury, rapidly accelerated renal failure, and gastrointestinal symptoms. The capillary leak syndrome, or rapid and massive loss of fluid from capillaries into the interstitial space, loss of peripheral vascular resistance, and subsequent multisystem end-organ failure further characterize this entity.

When epidemic disease was first described, TSS had unique geographic, age, sex, and racial characteristics. It was associated with menses, particularly tampon use, as

TABLE 64-1 Clinical Case Definition of Toxic Shock Syndrome

Clinical Findings

Fever: Temperature ≥38.9° C (102° F)

Rash: Diffuse macular erythroderma

Desquamation: 1-2 wk after onset of illness, particularly on palms, soles, fingers, and toes

Hypotension: Systolic blood pressure ≤90 mm Hg for adults; <5th percentile by age for children <16 yr old; orthostatic drop in diastolic blood pressure ≥15 mm Hg from lying to sitting; orthostatic syncope or orthostatic dizziness

Involvement of three or more of the following organ systems:
- Gastrointestinal: Vomiting or diarrhea at onset of illness
- Muscular: Severe myalgia or creatinine phosphokinase level greater than twice the upper limit of normal for the laboratory
- Mucous membrane: Vaginal, oropharyngeal, or conjunctival hyperemia
- Renal: BUN or serum creatinine greater than twice the upper limit of normal or ≥5 white blood cells per high-power field in the absence of a urinary tract infection
- Hepatic: Total bilirubin, AST, or ALT greater than twice the upper limit of normal for the laboratory
- Hematologic: platelets <100,000/mm^3
- Central nervous system: disorientation or alterations in consciousness without focal neurologic signs when fever and hypotension are absent

Negative results on the following tests, if obtained:
- Blood, throat, or cerebrospinal fluid cultures; blood culture may be positive for *Staphylococcus aureus*
- Serologic tests for Rocky Mountain spotted fever, leptospirosis, or measles

Case Classification

Probable: A case with 5 of the 6 clinical findings described above

Confirmed: A case with all 6 of the clinical findings described above, including desquamation, unless the patient dies before desquamation could occur

From Wharton M, Chorba TL, Vogt RL, et al. Case definitions for public health surveillance. *MMWR Recomm Rep* 1990;**39**(RR-13):1-43.

well as with a phenotypically distinctive type of *Staphylococcus aureus*. Patients with menses-associated TSS (menstrual TSS) had vaginal or cervical colonization with strains of *S. aureus*[21] that made a characteristic toxin initially called *staphylococcal enterotoxin F*[22] and *pyrogenic exotoxin C*[273] and now known as *TSST-I*. Cases of TSS not associated with menses (nonmenstrual TSS) were recognized with toxin-producing *S. aureus* isolated from a variety of sites, including burn and postsurgical wounds. Further, a toxic shocklike syndrome was recognized in patients with *Streptococcus pyogenes* infection.

TSST-I, staphylococcal enterotoxins, and streptococcal pyrogenic exotoxins A and B are now recognized to be "superantigens." These superantigens act as potent stimuli of T-cell proliferation by binding to selected V_β elements of the T-cell receptor and to major histocompatibility complex (MHC) class II receptors on antigen-processing cells. The resulting massive release of interleukin (IL)-1, IL-2, tumor necrosis factor-α (TNF-α), lymphotoxin (TNF-β), and interferon-γ mediates the manifestations of the disease.

EPIDEMIOLOGY

Surveillance and Incidence

The first 12 cases of epidemic TSS were identified in Wisconsin and Minnesota between July 1979 and January 1980 and were reported to the Centers for Disease Control and Prevention (CDC) in January 1980.[42,83,280] Surveillance for TSS began in Wisconsin[82] and Minnesota[234] in January 1980; in Utah in February 1980[180]; and in other states after the national communications about TSS in spring 1980. The National Center for Health Statistics recommended use of the International Classification of Diseases (ICD) code 040.89 for TSS, and a study found the sensitivity and specificity of using this code to identify cases was 85 and 95 percent, respectively.[142] In May 1980, the CDC reported findings of the first 55 cases,[42] 95 percent of which occurred in women. Of 40 patients for whom a menstrual history was obtained, 38 (95%) had onset during menstruation. By June 1980, case-control studies statistically linking the occurrence of menstrual TSS with tampons had been completed by the Wisconsin Division of Health[83] and the CDC,[280] and similar trends had been noted by the Utah Department of Health.[167] In September 1980, the CDC reported that TSS had been associated with many tampon brands, particularly Rely (Procter & Gamble). This brand was withdrawn with a documented decrease in reported cases.* In April 1985, two additional tampon manufacturers withdrew their superabsorbent tampons containing polyacrylate on the basis of an in vitro study[212] and a judicial decision.[226]

Between 1983 and 1994, the CDC received reports of 4192 cases of TSS through the National Electronic Telecommunications System for Surveillance (NETSS).[49] Of 2509 confirmed cases reported to the CDC through April 1984, 95 percent occurred in females,[253] 89 percent had an onset of TSS associated with menstruation, and 99 percent occurred in tampon users. In 1980 the reported rate of TSS was 2.4 to 12.3/100,000 women of menstruating age.[83,180,234,247] Since 1983, a continued downward trend in passively reported cases has been noted (Fig. 64-1).[323] The results of an active surveillance study conducted by the CDC in 1986 and 1987 confirmed the downward trend previously noted in the CDC passive surveillance system.[132] The incidence of menstrual TSS was found to be 1 case/100,000 women aged 15 to 44 years. Only 55 percent of the cases detected in the 1986 to 1987 study occurred in women, and only 45 percent of all cases were menstrual associated.[35,132] The TSS-related mortality rate for menstrual cases decreased from 5.5 percent in 1979 and 1980 to 2.8 percent in 1981 to 1986, then to 1.8 percent in 1987 to 1996.[138] The striking reduction in the incidence of menstrual TSS was attributed to a decrease in tampon absorbency, changes in

FIGURE 64-1 ■ Menstrual and nonmenstrual toxic shock syndrome cases reported to the Centers for Disease Control and Prevention by year, 1979 to 1996. (From Hajjeh RA, Reingold A, Weil A, et al. Toxic-shock syndrome in the United States: surveillance update, 1979-1996. *Emerg Infect Dis* 1999;**5**:807–10.)

composition of tampons and patterns of use, and the impact of publicity on early recognition of symptoms.*

As the incidence of menstrual TSS declined, the incidence of nonmenstrual TSS in women (0.25 case/100,000 women) and men (0.16 case/100,000 men) remained stable from 1980 to 1987, with nonmenstrual TSS accounting for a greater proportion of overall TSS cases. The proportion of nonmenstrual cases reported after surgical procedures increased from 14 percent during 1979 to 1986 to 27 percent during 1987 to 1996.[138] In 1994, of 192 cases of TSS reported to the CDC, 42 percent were nonmenstrual.[49] Overall the case-fatality ratio for nonmenstrual cases has remained between 5.3 and 8.5 percent.[35,49]

Since the 1980s, a surveillance study conducted from 2000 to 2006 in the Minneapolis–St. Paul area found that the TSS incidence has remained stable with the average annual incidence per 100,000 of menstrual TSS 0.69 (95% confidence interval [CI], 0.39-1.16) and nonmenstrual TSS 0.32 (95% CI, 0.12-0.67). Methicillin-resistant *Staphylococcus aureus* (MRSA) accounted for 7 percent of TSS cases.[94]

Although TSS cases in the United States have been reported in all 50 states, significant differences in incidence were noted among the states through 1983.[253] Through mid-1983, the five states of Wisconsin, Minnesota, Colorado, Utah, and California accounted for 44 percent of the total reported cases but represented only 16 percent of the U.S. population.[309] Although intensified surveillance may have been a factor, regional differences in the degree of immunity to TSS-associated *S. aureus* toxins and in the distribution of toxin-producing organisms may have been important factors.[243,317] Geographic differences in the occurrence of TSS continued even with the increase in the relative proportion of nonmenstrual cases.[35]

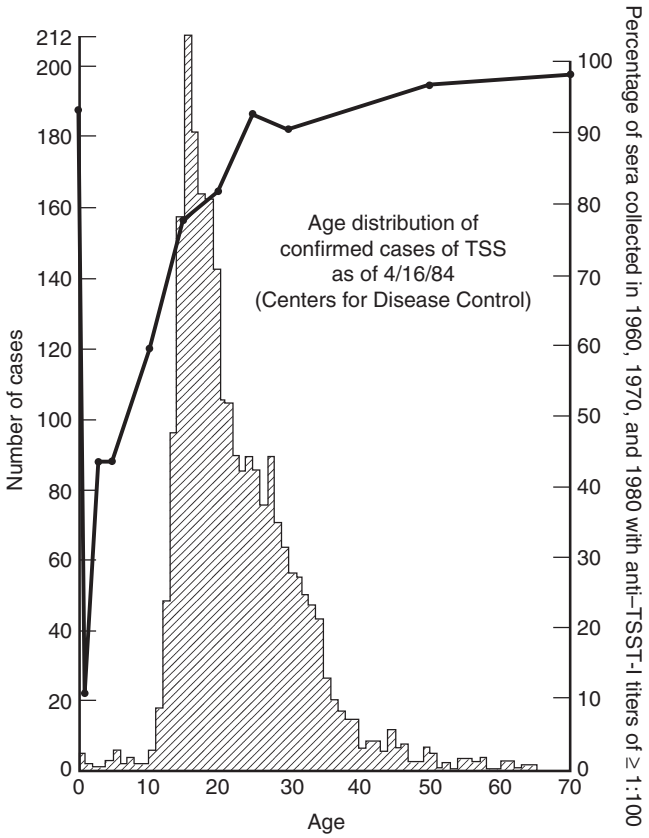

FIGURE 64-2 ■ Age distribution of patients with confirmed toxic shock syndrome (TSS) reported to the Centers for Disease Control and Prevention before April 16, 1984. The age-specific prevalence of antibodies to toxic shock syndrome toxin I (TSST-I) in a normal population in Wisconsin in the years 1960, 1970, and 1980 is indicated by the *solid connected line*. (Data from Vergeront JM, Stolz SJ, Crass BA, et al. Prevalence of serum antibody to staphylococcal enterotoxin F among Wisconsin residents: implications for toxic shock syndrome. *J Infect Dis* 1983; **148**:692–8.)

Risk Factors for Menstrual Toxic Shock Syndrome

From 1980 through 1990, most reported cases of TSS occurred in previously healthy, young white menstruating women who were using tampons at the time of onset of the illness. The risk for developing menstrual TSS is highest in the ages 15 to 25 years (median age, 21 years, 1979 to 1980; 20 years, 1981 to 1986; 25 years, 1987 to 1996).[132,138,253] Roughly one third of cases occur in adolescents 15 to 19 years of age (Fig. 64-2).[317] The precise reason for the increased incidence of TSS in adolescent girls is not known, but a lower prevalence of antibody to TSST-I may increase susceptibility in this age group.[317]

A striking 97 percent of menstrual TSS cases have occurred in whites, who make up 83 percent of the U.S. population. The reasons for racial differences are only partially explained by differences in menses-related practices.[118,253,254] Racial differences in antibody to TSST-I may explain to some degree the differences in the distribution of cases.[317]

Menstruation and tampon use were established as clear risk factors for the development of TSS.* Although TSS occurs with all brands of tampons, a greater relative risk for menstrual TSS was found with brands with higher absorbency and particular compositions.[41,268] The Tri-State TSS Study and subsequent studies by the CDC established that tampons of increasing absorbency were associated with an increasing relative risk for the development of menstrual TSS; for each 1-g increase in absorbency, the risk for TSS increased by 34 to 37 percent.[23,122,232] In addition, the studies suggested that the effects of absorbency and chemical composition of tampons on TSS risk were independent.[35,232] Continuous use of tampons was associated with a greater risk for the development of TSS in one case-control study,[280] but this finding was not confirmed in a subsequent investigation.[232] No association between TSS and the frequency of changing tampons has been demonstrated.

On June 22, 1982, a U.S. Food and Drug Administration (FDA) regulation required that information on TSS and tampon-associated risks appear on tampon packages.[97] Since 1980, tampon composition has changed to cotton and rayon combinations with the removal of additives such as polyacrylate, polyester foam, cross-linked carboxymethylcellulose, and surfactants, including Pluronic L-92.[270] In 1980, products very high in absorbency were used by 42 percent of tampon users.[234] By 1983, this proportion had decreased to 18 percent and, by 1986, to 1 percent.[48] Overall, the absorbency of available tampon brands decreased from 10.3 to 20.5 g in 1980 to less than 6 to 15 g in 1990. In 1990, the FDA published the in vitro rating system to be used by manufacturers to inform the public about tampon absorbency.[187,221,314]

Risk Factors for Nonmenstrual Toxic Shock Syndrome

The mean age of patients with nonmenstrual TSS (27 years through 1982, 30 years in 1986) is significantly higher than that for menses-associated cases.[132,254] The number of confirmed cases of TSS reported in children younger than 10 years of age is surprisingly low, particularly in light of their demonstrated low antibody titers to TSST-I and the increased prevalence of nasal colonization (10%) with TSST-I–positive strains.[35,158,317,327] The racial distribution is less pronounced, with 87 percent occurring in whites, who make up 83 percent of the U.S. population, and the ratio of males to females with nonmenstrual TSS is closer to that in the general population.[253,254]

Data on risk factors (Table 64-2) was obtained for 559 nonmenstrual TSS cases reported to the CDC through 1986.[35] Associated infections or procedures included nonsurgical cutaneous and subcutaneous infections, 22 percent; childbirth or abortion, 15 percent; infections after a wide variety of surgical procedures, 15 percent; vaginal infections occurring at times other than during menses, 6 percent; vaginal contraceptive sponge use, 5 percent[78]; diaphragm use, 6 percent; and other or unknown sources of infection, 31 percent.

TABLE 64-2 Risk Factors for Nonmenstrual Toxic Shock Syndrome

I. Colonization with toxin-producing *Staphylococcus aureus*
II. Absence of protective antitoxin antibody
III. Infected site
  A. Primary *S. aureus* infection
    Carbuncle
    Cellulitis
    Dental abscess
    Empyema
    Endocarditis
    Folliculitis
    Mastitis
    Osteomyelitis
    Peritonitis
    Peritonsillar abscess
    Pneumonia
    Pyarthrosis
    Pyomyositis
    Sinusitis
    Tracheitis
  B. After surgery: wound infection
    Abdominal
    Breast
    Cesarean section
    Dermatologic
    Ear, nose, and throat
    Genitourinary
    Neurosurgery
    Orthopedic
  C. Skin or mucous membrane disruption
    Burns (chemical, scald, etc.)
    Dermatitis
    Influenza
    Pharyngitis
    Postpartum (vaginal delivery)
    Superficial/penetrating trauma (insect bite, needle stick)
    Viral infection
    Varicella
  D. After surgical or nonsurgical foreign body placement
    Augmentation mammoplasty
    Catheters
    Diaphragm
    Sponge (contraceptive)
    Surgical prostheses/stents/packing material/sutures
  E. No obvious focus of infection (vaginal or pharyngeal colonization)

The three risk factors necessary for the acquisition of nonmenstrual disease include colonization (or acquisition) of a toxin-producing strain of *S. aureus*, absence of protective antitoxin antibody, and an infected site. TSS has been reported in association with *S. aureus* infections of almost every type, including primary staphylococcal infections and those occurring after surgery, infections associated with disruption of skin or a mucous membrane, and infections occurring after placement of a foreign body (see Table 64-2).[21] Numerous patients with

TSS have been reported for whom no obvious focus of infection was found.[35,254] Trauma or surgery in areas of the body frequently colonized with *S. aureus* (nose, skin, vagina) places individuals at enhanced risk for infection and subsequent TSS.

Host Risk Factors: General

Colonization with Exotoxin-Producing *Staphylococcus aureus*

For TSS to develop, an individual must be colonized with or acquire a strain of *S. aureus* that produces TSST-I or one of the staphylococcal enterotoxins. Evidence that staphylococcal enterotoxin B alone and, uncommonly, staphylococcal enterotoxin A or staphylococcal enterotoxin C alone, as well as TSST-I, may be responsible for the manifestations of TSS is compelling. Although many genotypically different strains of *S. aureus* possess the *tst*H gene, one clone has been isolated from 88 percent of menstrual cases and 54 percent of nonmenstrual cases.[218]

Absence of Protective Antibody Levels

A necessary factor for the development of TSS is the absence of protective antibody levels for the toxin (TSST-I or enterotoxin) produced by the isolate associated with TSS. Thus, more than 90 percent of women with menstrual TSS associated with TSST-I–positive strains have antibody titers of 1:10 or lower, whereas a titer of 1:100 or higher is considered protective.[21] Because most adults acquire these antibodies without the development of disease, absent antibody levels may be the result of lack of exposure to a toxin-producing organism or a lacunar inability to respond to the toxin. The failure of most patients, menstrual and nonmenstrual, to form antibody during convalescence may reflect this lacunar nonrecognition of staphylococcal protein antigen, or it may be a reflection of the superantigenic nature of these proteins and failure of the toxin proteins to be presented to the T-cell receptor as conventional antigens. In mice and one patient with TSS, in vivo TSST-I–induced proliferation was followed by hyporesponsiveness of TSST-I–responsive $V_\beta 2^+$ T cells.[186]

Interruption of a Mucosal or Skin Surface

Primary deep-tissue staphylococcal infections (e.g., osteomyelitis, pyarthrosis, pyomyositis,[4] endocarditis,[248,324] renal carbuncles, and bacteremia) rarely are associated with TSS. Most nonmenstrual cases occur in patients with an altered skin or mucosal surface. Examples of skin disruption associated with TSS include burns, insect bites, needle sticks, surgical incisions, and varicella. Cases of disruption of mucous membranes can be divided into those associated with respiratory mucosae and those associated with genital mucosae. Damage to respiratory mucosa may occur after nasal or other surgery, particularly with placement of stents or packing, in association with a viral respiratory tract infection such as influenza, or as a result of primary sinusitis, tracheitis, or a parapharyngeal abscess. Heavy colonization of the pharynx also has been associated with TSS. The vaginal mucosa may be damaged in numerous ways, including during placement of tampons or barrier contraceptives,[46,112,277] postpartum,[22,238] or after genital surgery or genital mucosal damage.[113,236,261] Heavy colonization of the vagina without any other apparent risk factor likewise has been associated with TSS.[254] These mucosal infections may provide the right conditions for production of TSST-I, including an aerobic environment, high carbon dioxide concentration, neutral pH, high protein and low glucose concentrations, and low to normal magnesium concentration.[212]

Presence of a Foreign Body

Tampons create an aerobic environment in the vagina, which normally is anaerobic. Tampons of three different types have been shown in humans to change the partial pressure of oxygen of the vaginal wall from an anaerobic environment to that of atmospheric air throughout the 90-minute interval after insertion.[319] Because oxygen is required for the production of TSST-I, researchers have suggested that tampons with enhanced absorbency allow the introduction of increasing concentrations of oxygen to enhance production of toxin.

Several alternative explanations for the role of tampons have been proposed. Tampons may remove vaginal substrates that normally inhibit the growth of *S. aureus*.[21] Another suggested role for tampons is that of inducing cervicovaginal ulceration. Such ulcers have been suggested to enhance bacterial growth or toxin absorption and expose submucosal fibronectin for binding of *S. aureus*.[73,75,322] Tampons can induce chronic cervicovaginal ulcers after long-term continuous use or superficial microulcerations after a brief insertion in otherwise healthy women. However, vaginal ulcerations of the type typically seen in TSS have been found during postmortem examination in women who had never used tampons. This finding suggests that vaginal ulceration, such as that seen in the esophagus and bladder in TSS, may be induced by TSST-I.[179]

Investigations to determine whether individual tampon components can induce the production of TSST-I in vitro have provided conflicting data, in part because no consensus exists on how best to test tampon components to determine their potential to increase risk for development of TSS. In one setting, although bacterial growth was unaffected, production of TSST-I varied from undetectable levels to 300 μg/mL, depending on the tampon studied.[21] Other investigators have found that most tampons tested were inhibitory to both bacterial growth and production of TSST-I and that none consistently increased the production of TSST-I.[21] Two studies clearly demonstrated enhanced production of TSST-I in vitro by the Rely tampon, which is composed of cross-linked carboxymethylcellulose and polyester foam.[241,272] The polyacrylate rayon and surfactant Pluronic L-92 included in some tampons brands increased the production of TSST-I under certain conditions.[211,272] Neither cotton nor rayon amplifies the production of TSST-I in vitro, nor do cotton tampons adsorb TSST-I or prevent its

production.[241,272] Thus, cotton tampons cannot be claimed to be safer than cotton and rayon combinations, although this contention has been disputed.[303]

Implanted foreign material, including sutures, central venous lines, metallic or polymeric implants, Teflon splints, and gauze packing, have been documented repeatedly to enhance the risk for acquiring bacterial infection.[21,160] These infections are characterized by limited spread beyond the tissues in immediate contact with the implants, poor response to antibiotics, and poor healing without removal of the foreign material. Two important differences between TSS and other *S. aureus* infections related to foreign material are the added ability of the organism to produce a toxin that readily disseminates and the limited ability of these strains to produce inflammation.[114] Researchers have suggested that the increased number of surgically associated TSS cases may be related to the number of implanted materials.[138]

The enhanced risk for acquiring infection by *S. aureus* in the presence of foreign material has been defined experimentally in animals. Rats remained asymptomatic after the subcutaneous injection of more than 1×10^6 colony-forming units of *S. aureus*, whereas 3×10^2 colony-forming units invariably led to infection in the presence of a suture. In addition, the ability of sutured tissue to resist infection varies with the kind of material implanted, particularly its physical or chemical configuration. For example, bacterial adherence is eightfold higher for braided sutures of silk, silicone-heated blue polyester, and absorbable polyglycolic acid than for monofilament nylon.[160]

Other Potential Host Risk Factors

Other factors have been examined in an attempt to identify individuals who may be at increased risk for the development of TSS.[86] Some of these factors have included human leukocyte antigen type,[21] neutrophil function,[145] adherence of *S. aureus* to vaginal epithelial cells,[20] alteration of the cervicovaginal flora,[21] hormonal factors, and personal hygiene practices.[86] Of all of these factors, those of potential importance included cervicovaginal flora and hormonal factors.

Vaginal co-colonization with *S. aureus* and Enterobacteriaceae has been postulated to enhance the risk for development of TSS.[62] Prospective examination of 495 healthy women revealed a 7 percent vaginal colonization rate for *S. aureus* TSST-I–positive strains. Women who were colonized with toxin-producing *S. aureus* had higher rates of colonization with *Escherichia coli* or other Enterobacteriaceae. *E. coli* isolation rates were 54 percent in women with TSST-I–positive isolates, 15 percent in women with TSST-I–negative isolates, and 11 percent in women with no *S. aureus*. Among the 14 patients with TSS monitored in this study, 9 had *E. coli* as well as TSST-I–positive *S. aureus* co-isolated during the acute TSS episode. The significance of these observations and their relationship to postulated roles for endotoxin in TSS are not clear.

The results of early case-control studies suggested that oral contraceptive steroids might have an effect on vaginal *S. aureus* organisms that may produce or release TSS-associated toxins[83,195,233] and that this effect was protective. However, one case-control study found no protective effect or enhanced risk associated with oral contraceptive use.[132] Hormonal control is known to be responsible for numerous cyclic changes in vaginal pH and flora, but the role of hormonal factors in the pathogenesis of TSS has not been examined well.

HISTOPATHOLOGY

The histopathologic findings on postmortem examination support the concept that TSS is a toxin-mediated disease.* Striking histopathologic similarities exist between patients with TSS and those with "scarlet fever" reported in 1936.[33] Typically, a total absence of tissue invasion by bacteria and minimal evidence of an inflammatory reaction in most organs are noted. Findings thought to be due to a direct effect of the toxin or mediators (or both) and unrelated to hypoperfusion include subepidermal ulcerations in the cervix, vagina, esophagus, and bladder; depletion of lymphocytes in lymph nodes; a subepidermal cleavage plane in the skin; and mild inflammatory changes in the kidney, liver, heart, and muscle.

Cervicovaginal ulcerations are the only characteristic lesions noted in the genital tract of patients with fatal menstrual TSS, and such ulcers have been found in a patient with menstrual TSS who had never used tampons.[179,238] The ulcerations are superficial. Capillary vasodilation and thrombosis with inflammation of the mucosa are present, but no deep-tissue bacterial invasion is seen. The layer of vacuolization and separation in the ulcers occurs beneath the basal layer. The same type of ulcer also has been found in the bladder and esophagus, which suggests that these ulcerations may be caused by the toxins or mediators and not by the use of tampons.

Although the myocardium was described as normal in one postmortem series of TSS, in another series of eight fatal cases, all patients had evidence of focal round-cell infiltration with variable degrees of congestion, edema, and hemorrhage.[179,235] Myxoid degeneration was found in all heart valves from four patients in one series. Sections of skeletal muscle have demonstrated only congestion, edema, focal hemorrhage or fiber necrosis, and a mild acute inflammatory infiltrate.

Varying degrees of triaditis or periportal lymphocytic inflammation have been the most consistent findings in the liver; centrilobular congestion with necrosis and mild cellular degeneration also has been described.[155] In the kidney, toxin-mediated mononuclear interstitial nephritis may result from perivasculitis of the adventitia of the renal venules, lesions that probably precede the development of hypotension-induced acute tubular necrosis. The most characteristic findings in the spleen and lymph nodes have been lymphocyte depletion; inactive hypocellular, hypoplastic lymphoid follicles with edema; marked histiocytosis in the interfollicular areas; and hemophagocytosis.

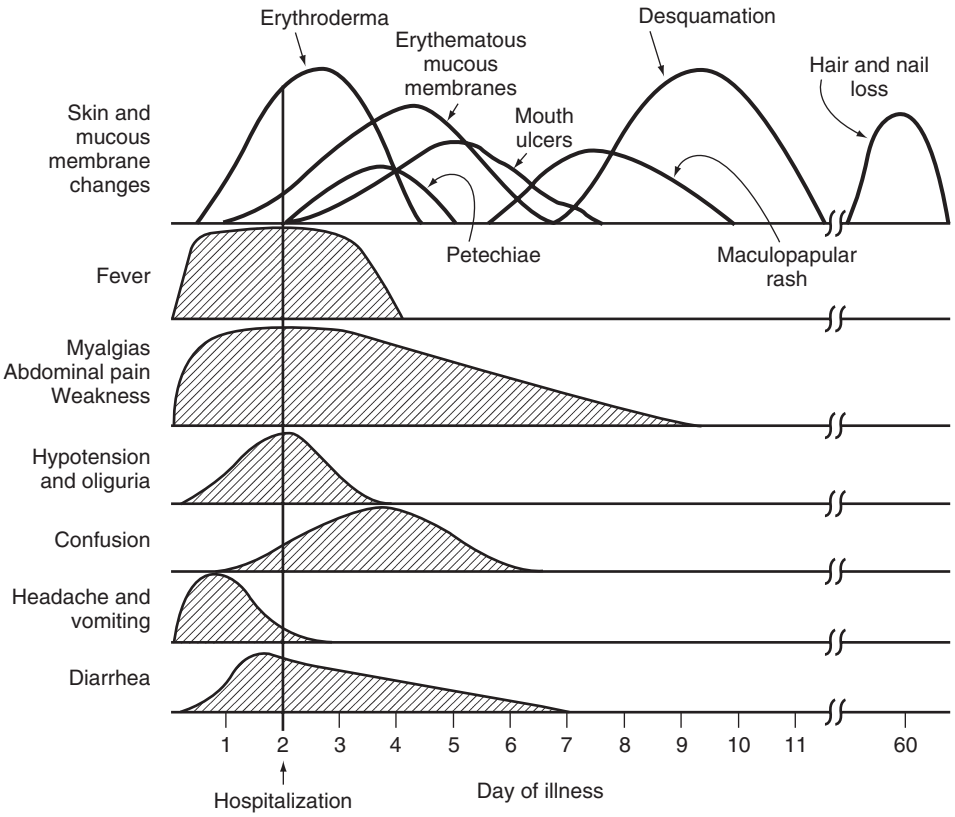

FIGURE 64-3 ■ Composite drawing of the major systemic skin and mucous membrane manifestations of toxic shock syndrome. (From Chesney PJ, Davis JP, Purdy WK, et al. The clinical manifestations of toxic shock syndrome. *JAMA* 1981;**246**:741–8. Copyright 1981, American Medical Association.)

Perivascular lymphocytic infiltrates and bullae that separate at the basement membrane are characteristic of the early skin changes in TSS.[8,10,145] No evidence of vasculitis has been reported.

CLINICAL SPECTRUM

Acute Phase: Moderate to Severe Disease*

The manifestations in TSS are the result of release of endogenous mediators after monocyte and T-cell activation by TSST-I or the staphylococcal enterotoxins. The physiologic changes induced by this dysregulation of the immune system are striking in their rapidity of onset and progression and the involvement of almost all body tissues and organs.

Multisystem end-organ damage secondary to loss of peripheral vascular resistance, loss of intravascular volume as a result of endothelial damage and the capillary leak syndrome, and interstitial edema constitute the most important mediator-induced changes of TSS. Prolonged hypotension, interstitial edema, and vascular congestion additionally may result in ischemic organ damage.

The onset of illness in patients with moderate to severe disease is abrupt, with signs and symptoms including fever, chills, malaise, headache, sore throat, myalgia, muscle tenderness, fatigue, vomiting, diarrhea, abdominal pain, and orthostatic dizziness or syncope (Figs. 64-3 and 64-4).

During the first 24 to 48 hours, diffuse erythroderma, severe vomiting and watery diarrhea (often with incontinence), decreased urine output, cyanosis, and edema of the extremities may be noted. Some patients may have purpura fulminans.[172] Cerebral ischemia and edema rapidly result in somnolence, confusion, irritability, agitation, and occasionally hallucinations, even in individuals without hypotension. Patients with TSS have had signs and symptoms of encephalopathy, cerebral infarction, meningismus,[15,25,140,184,285] and the cauda equina syndrome.[8]

On initial physical examination, fever, tachycardia, tachypnea, hypotension, erythroderma (generally not seen in patients with severe hypotension or in those without T cells)[164] (see Fig. 64-4A), and muscle tenderness are noted in conjunction with peripheral cyanosis and edema, conjunctival hyperemia, subconjunctival hemorrhages (see Fig. 64-4B), beefy red edematous mucous membranes, somnolence, disorientation, and agitation. In menstrual TSS, edema and erythema of the inner aspect of the thighs and the perineum may be noted in conjunction with normal findings on uterine and adnexal examination. In nonmenstrual cases, vaginitis or another focus of infection will be present. In most postoperative cases, the surgical wound is not inflamed. If

FIGURE 64-4 ■ Skin and mucous membrane manifestations present at the onset of toxic shock syndrome (TSS). **A,** Diffuse erythroderma in a 7-year-old child with nonmenstrual TSS associated with osteomyelitis of the fibula. **B,** Bulbar conjunctival infection and subconjunctival hemorrhage in a 24-year-old woman with nonmenstrual TSS. (**B** from Bach MC. Dermatologic signs in toxic shock syndrome: clues to diagnosis. *J Am Acad Dermatol* 1983;**8**:343–7.)

erythroderma is present, it will be most intense surrounding the infected focus.

Surgical wounds and some abscesses colonized or infected with *S. aureus* and responsible for postoperative or nonmenstrual TSS may have minimal or no signs of inflammation.[6,17,100,254] The production of TNF-α by macrophages in response to TSST-I inhibits neutrophil mobilization in vitro,[114] which may provide an explanation for the absence of signs of inflammation. The incubation period for postoperative or postpartum TSS may be as short as 12 to 48 hours. Relatively few cases have been associated with deep-tissue infection.[21]

Laboratory Findings

Laboratory tests reflect the endogenous cytokine release, shock, and organ failure associated with TSS. Leukocytosis may not be present, but the proportion of neutrophils generally exceeds 90 percent. The proportion of immature neutrophils usually is 25 to 50 percent of the total number of neutrophils and is associated with absolute lymphopenia. Thrombocytopenia and anemia are present during the first few days and frequently are accompanied by prolonged prothrombin and partial thromboplastin times. Disseminated intravascular coagulation may be present. Sterile pyuria and cerebrospinal fluid pleocytosis are indicative of generalized involvement of the mucous membranes and serosal surfaces. Elevated blood urea nitrogen and creatinine levels reflect kidney damage,[57] and abnormalities in tests of liver function reflect liver damage and acute cholestasis.[135,155] Hypoproteinemia and hypoalbuminemia reflect capillary leak, and profound hypocalcemia may reflect both hypoproteinemia and high serum levels of a calcitonin-like material.[58,288] Muscle involvement is noted by an elevated creatine phosphokinase level, and the hypophosphatemia that occurs despite impaired renal function is unexplained.[14,58] Most of these test results will return to normal within 7 to 10 days of disease onset. *S. aureus* will be cultured from the cervix or vagina in more than 85 percent of patients with menstrual TSS and from the focus of infection in patients with nonmenstrual TSS. Positive blood culture results are rare findings.[74] Antibody to TSST-I or to the staphylococcal enterotoxins

will be absent at the onset of disease in more than 85 percent of patients.*

Diagnosis

Application of the case definition for a single episode[323] or recurrent episodes[84] to the patient's illness is currently the only way to confirm the diagnosis (see Table 64-1). Aggressive attempts to find the focus of *S. aureus* include culture of the cervix and vagina in patients with menses-associated illness and culture of other potentially infected sites in patients with nonmenstrual illness. *S. aureus* isolates can be examined for their ability to produce TSST-I, although such testing seldom is indicated. This test is of limited usefulness for nonmenstrual cases because TSST-I is produced by only 40 to 60 percent of *S. aureus* isolates from such patients.[131] Isolates from these patients can be examined for the presence of the other enterotoxins. Acute and convalescent sera can be tested for the presence of antibodies to TSST-I and the other enterotoxins.[149] Elevated levels of anti–TSST-I in the acute-phase serum of a patient with menstrual-associated TSS would be highly unusual.

In most instances, toxin detection tests are of value only for research or for patients with chronic recurrent or atypical disease. Genes for TSST-I and the enterotoxins have been detected in *S. aureus* strains by polymerase chain reaction† and hybridization techniques.[161,220,231] A noncompetitive enzyme-linked immunosorbent assay allows quantitation of TSST-I in clinical samples.[199,213] Reversed passive latex agglutination has been used in hospital laboratories to detect TSST-I and in research laboratories to detect enterotoxins.[89,111] Research laboratories also have developed techniques for detecting the selective expansion of $V_\beta 2$-positive T cells as evidence of host response to superantigenic toxins.[61,191]

Treatment

The four general principles of treatment of TSS (Table 64-3) are (1) identification and drainage of the focus of toxin production, (2) identification and susceptibility testing of the organism, (3) administration of antimicrobial therapy to block synthesis of the toxin and kill *S. aureus*, and (4) management of the systemic multiorgan actions of the toxins or mediators.‡

Location and Drainage of the Infected Site. The focus of infection should be identified rapidly, any foreign bodies should be removed, and the site should be drained or irrigated completely, even if it does not appear to be inflamed. Performing this procedure is of utmost importance because perpetuation of even a small, undrained focus of infection may result in serious clinical consequences. If TSS occurs in the immediate postoperative period, the wound should be assumed to be the source of infection, regardless of its benign appearance.

TABLE 64-3 **Therapeutic Principles for Management of Toxic Shock Syndrome**

1. Identify the focus of infection: Débride and irrigate extensively and remove any foreign material
2. Isolate the organism for antimicrobial susceptibility studies
3. Administer parenteral antimicrobial therapy
   Stop enzyme or toxin production with a protein synthesis inhibitor (e.g., clindamycin, erythromycin, gentamicin)
   and
   Eradicate the organism with a bacterial cell wall inhibitor (e.g., β-lactamase–resistant antistaphylococcal antimicrobial agent)
   Consider intravenous immunoglobulin to provide antitoxin antibodies for a subset of patients, including those with the following:
   - Disease refractory to initial fluid replacement and several hours of vasopressor support
   - A focus of infection that cannot be drained
   - Persistent oliguria despite massive fluid replacement and in the presence of pulmonary edema

   Consider additional measures, such as the following:
   - Methylprednisolone to suppress cytokine production and the inflammatory response
   - Fluid therapy to maintain adequate venous return and cardiac filling pressure and to prevent end-organ damage
4. Anticipate the management of multisystem organ failure

Identification and Susceptibility Testing of the Organism. The incidence of community-acquired MRSA infections has increased dramatically during the past 10 years.[134] These MRSA strains differ from the long-standing hospital-acquired MRSA strains in that they are acquired in the community by well individuals with no risk factors and are not multiresistant. Most strains are susceptible to clindamycin. Because MRSA strains are fully capable of producing TSST-I,[96,274] community-acquired menstrual and nonmenstrual cases of TSS may be caused by either community or multiresistant hospital-acquired strains of MRSA.[103] To date, vancomycin-resistant strains of *S. aureus* are rare findings.[50,148] Thus, every effort should be made to obtain the organism for susceptibility testing.

Administration of Antimicrobial Agents. Administration of antistaphylococcal antibiotics is indicated to eradicate organisms and prevent recurrence.[83,84] The infection may be a superficial or deep-tissue infection and may be associated with *S. aureus* bacteremia or bacteriuria. Antistaphylococcal antimicrobial agents should be administered intravenously at maximal doses for age as soon as possible. Once the patient is stable, high doses of an oral antimicrobial agent to which the organism is susceptible can be given to complete a total course of 10 to 14 days.

Subinhibitory concentrations of the protein synthesis inhibitors clindamycin, erythromycin, clarithromycin, kanamycin, gentamicin, tetracycline, and linezolid have been shown to suppress TSST-I production in

*References 22, 30, 71, 263, 283, 325.
†References 19, 162, 183, 198, 223, 275.
‡References 55, 63, 83, 84, 120, 122, 144, 196, 268, 290, 311.

vitro.[95,240,271,293] In one study, clindamycin concentrations 1/64 the minimal inhibitory concentration (MIC) were effective in totally blocking TSST-I production.[240] In a mouse model of myositis caused by *S. pyogenes*, another superantigen-producing organism, clindamycin and erythromycin were more efficacious than penicillin.[104,291,294]

Data suggest that subinhibitory concentrations of β-lactam antibiotics actually may *increase* TSST-I production by *S. aureus*. At a concentration of half the MIC, nafcillin can *increase* toxin production 10-fold more than under control conditions.[5] The effect is not seen with vancomycin, another cell wall–active drug, thus suggesting specificity beyond merely a cell wall effect. Coadministration of a protein synthesis inhibitor with a β-lactam antibiotic blocks the effect.[5]

The choice of initial empirical antimicrobial therapy has become more complex as a result of an increase in the number of community-acquired MRSA infections and the spread of multiresistant MRSA strains in hospitals.[166] In the past, the most effective initial empirical therapy was a combination of a β-lactamase–resistant penicillin and clindamycin. With recent concern for MRSA strains causing TSS, consideration should be given to initiating therapy with vancomycin and clindamycin. As an alternative for MRSA coverage, linezolid has been used successfully for treatment of staphylococcal TSS.[293] Once the results of susceptibility testing of the organism are available, therapy can be adjusted appropriately.

Management of Systemic Multiorgan Actions of the Toxins or Mediators

Intravenous Immunoglobulin and Toxin Inhibition. Given the high prevalence of antibodies to TSST-I in adults,[317] high levels of antibody to TSST-I are present in intravenous immunoglobulin (IVIG) preparations.[54,59,200,238,301] In animal models of TSS, human IVIG given at the time of inoculation of TSST-I–positive *S. aureus* prevented the development of TSS. When IVIG was administered 8 hours later, it decreased the mortality rate from 90 percent in control rabbits to 16 percent. When IVIG was given 29 hours after administration of TSST-I, the increase in survival rates in the IVIG-treated animals still was significant. No adverse reactions were noted in the treated animals, and no evidence was found of disease mediated by the formation of antigen-antibody complexes.[200-204] Monoclonal antibodies to TSST-I can prevent the development of manifestations of TSS in the rabbit model completely.[31,242,278]

High concentrations of antibodies to TSST-I and the staphylococcal enterotoxins (type A; type B; types C 1, 2, and 3; type D; and type E) have been demonstrated in pooled IVIG.[54,59,238,301] These antibodies may inhibit the binding of toxins to MHC class II antigen-processing cells or interfere with presentation of toxin by these cells to the T-cell receptor. As a result, production of TNF-α and TNF-β is inhibited by these antibodies in vitro in an apparent toxin-specific manner.[301]

The results of these in vitro studies have supported the use of IVIG for staphylococcal TSS.[257] Anecdotal case reports have indicated a beneficial effect on staphylococcal[16,59,67,202,225,238] TSS in humans. Because IVIG is expensive and most patients respond rapidly once standard therapeutic measures are initiated, some authors would reserve IVIG for patients with an inaccessible focus of infection or for those who continue to deteriorate after receiving fluid and vasopressor support for several hours (see Table 64-3). The dose most often used has been 400 mg/kg given as a single dose over the course of several hours. This dose results in a serum antibody titer of greater than 1:100, much higher than that appearing to provide immunity to TSST-I.[238] Some studies have used IVIG doses of up to 2 g/kg.[77] Because early administration of IVIG possibly could blunt the immune response to TSST-I or other toxins and increase the possibility of a recurrent episode, the potential risks and benefits of this form of therapy must be considered for each patient.

The role of endotoxin in the pathogenesis of TSS is unclear. The failure of polymyxin B and anti-J5 antiserum to alter the course of TSST-I–positive TSS in a rabbit model suggests that endotoxin may not be an important mediator of TSS.[203] Early and sporadic case reports of TSS suggested therapeutic benefit with naloxone,[65] calcium,[238] and exchange transfusion in severely ill patients unresponsive to the usual forms of therapy.

Corticosteroids. Short courses of methylprednisolone or dexamethasone, if given early in the course of the disease, have been associated with a reduction in the duration of fever and the severity of illness but no reduction in mortality rates.[307] In vitro, dexamethasone has been shown to downregulate TSST-I–induced cytokine production.[171] Because no controlled prospective study has demonstrated efficacy, the use of steroids probably should be restricted to hypotensive patients unresponsive to fluid resuscitation, antimicrobial agents, and IVIG.

Fluid Replacement. The most important aspect of the nonspecific treatment of symptomatic patients is fluid replacement.[304] Intravascular volume and cardiac filling pressure must be restored rapidly to achieve adequate tissue perfusion. Because of the ongoing capillary leakage, this fluid replacement may far exceed the estimated fluid requirements based on calculated maintenance and fluid deficit volumes. Some adults have required vasopressors and as much as 12 L of fluid during the first 24 hours to stabilize the circulating blood pressure. Pleural, pericardial, and peritoneal effusions and interstitial edema inevitably occur as a result of the continued vascular capillary fluid leak. Close monitoring in an intensive care unit will facilitate treatment of intravascular fluid loss, myocardial dysfunction, hemodynamic derangements, pulmonary edema, acute respiratory distress syndrome, acute renal failure, encephalopathy, and disseminated intravascular coagulation.

Subacute Phase: After Treatment Is Initiated

Once treatment is initiated, response usually is rapid, with defervescence within 48 hours. The hemodynamic changes are observed initially as tachycardia, decreased systemic vascular resistance, decreased central venous pressure, hypovolemia, normal pulmonary artery wedge pressure, and an increased cardiac index.[13,38,72,120,123] Once

aggressive fluid therapy has been initiated, myocardial edema and potential failure, along with pulmonary and cerebral edema in the face of renal failure, become the most critical management issues. The reasons for myocardial failure are unclear but probably are related to perivascular inflammation of the coronary vessels, edema, and postulated myocardial depressant factors.[179,235] TSST-I has been shown to inhibit systolic function in isolated rabbit atria, though at higher than usual circulating concentrations.[229] Arrhythmias may result from myocardial damage or electrolyte abnormalities.[197,259]

During the decompensated stage of myocardial dysfunction, the cardiac index falls and pulmonary wedge pressure increases, with both left atrial and ventricular and diastolic diameters being at the upper limits of normal.[120] Reversible electrocardiographic findings include sinus tachycardia, diffuse loss of voltage, flattened T waves, and diffuse nonspecific ST-T wave changes. If fatal arrhythmia does not occur during the decompensated stage, the toxic cardiomyopathy is reversible and rarely results in permanent changes. This process is similar to "stunned myocardium," a transient, postischemic myocardial dysfunctional state.[72]

Pulmonary edema and acute respiratory distress syndrome occur commonly in patients with severe disease when massive fluid replacement is necessary and the capillary leak syndrome continues in the lungs. Pulmonary edema appears rapidly once fluid replacement is initiated and often necessitates intubation and respirator management for several days.[304]

Forms of TSS-associated acute renal failure include prerenal azotemia and both nonoliguric and oliguric renal failure.[57] The type of renal failure manifested may depend on the degree of intravascular volume depletion. Unless severe acute tubular necrosis necessitates temporary hemodialysis, repletion of intravascular volume usually results in rapid restoration of renal function and, ultimately, diuresis. Permanent renal damage is an extremely rare event.[54]

The gastrointestinal, musculoskeletal, and hepatic changes resolve rapidly. Sequelae associated with these changes are rare, except for prolonged muscle weakness.[54,85] Joint manifestations generally are self-limited.[21,125]

Management of fluids, electrolytes, and metabolic acidosis in patients with TSS is complex. Although tetany is a rare occurrence, severe hypocalcemia may be life-threatening and should be corrected.[58,238,288] Most patients require potassium replacement and management of metabolic acidosis. The use of colloid for fluid replacement and removal of the toxin stimulus for capillary leak syndrome ultimately correct the hypoproteinemia.

The typical dermatologic manifestations follow a predictable sequence (see Fig. 64-3). A dandruff-like flaky desquamation begins on the trunk and extremities 5 to 7 days after the onset of symptoms. From days 10 to 12 and for as long as a month, the characteristic full-thickness desquamation of the fingers, toes, palms, and soles takes place (Fig. 64-5). A variety of atypical dermatologic manifestations, including petechiae and subepidermal bullae, have been described.[10,108,151]

Early in the acute phase, many patients exhibit desquamation of the mucous membranes, which is particularly painful when the oral mucous membranes are involved.[55] In addition, a small number of patients will have reactivated herpes simplex virus type 1 or 2 lesions with the acute illness.[55] A late-onset pruritic maculopapular rash with edema and low-grade fever probably unrelated to antimicrobial therapy occurs in more than 50 percent of menses-associated cases within 7 to 14 days of disease onset.[55,90] The cause of this late-onset rash is unknown.

Telogen effluvium, a common sequela, is a nonspecific response to trauma, sepsis, or stress that results in disturbed metabolism and keratinization of the hair follicles and nails. The hair follicles appear to transform prematurely from the growth, or anagen, phase to the telogen, or resting, phase. Hair and nail loss occurs 4 to 16 weeks after onset of the illness, with restoration taking place in 5 to 6 months.[21,24,55]

The hematologic system seldom is involved with major complications in TSS. Although disseminated

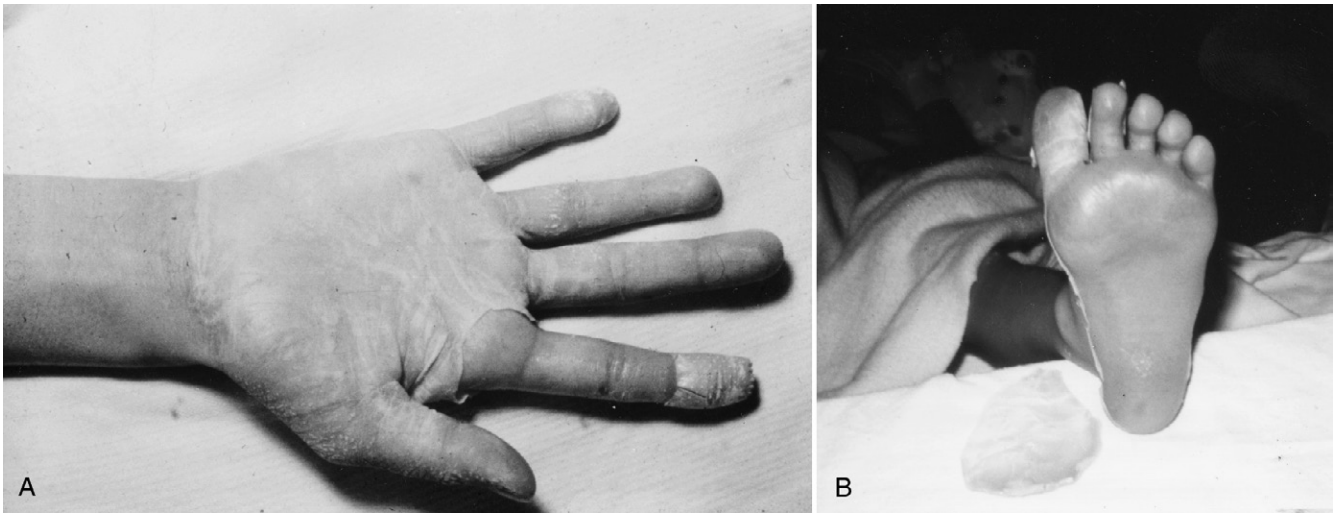

FIGURE 64-5 ■ Universal full-thickness desquamation of the hands **(A)** and feet **(B)** first noted 7 to 14 days after disease onset and persisting for up to 30 days.

intravascular coagulation may be present, gastrointestinal, uterine, or cerebral bleeding rarely occurs. Thrombocytopenia may be present initially in patients with disseminated intravascular coagulation; thrombocytosis is characteristic of the recovery phase. Mild to moderate normocytic, normochromic anemia, which probably is dilutional and a result of suppressed red blood cell synthesis, develops in virtually all moderately to severely ill patients with TSS and resolves during convalescence.[53,55] Hypoferrinemia occurs commonly.[53]

The relatively common toxic or ischemic encephalopathy, rarely complicated by seizures, resolves slowly during the first 4 to 5 days of hospitalization.

Outcome and Sequelae

Death associated with TSS usually takes place within the first few days of hospitalization, but it may occur as late as 15 days after admission. Fatalities have been attributed to refractory cardiac arrhythmias, cardiomyopathy, irreversible respiratory failure, and, rarely, bleeding caused by coagulation defects.[179,235] The duration of circulation of toxins and mediators and the associated hypotension may be the best predictors of the severity of the end-organ damage.

After being discharged, many patients experience prolonged fatigue, muscle weakness, and pain.[54] Sequelae that appear to be related to a prolonged period of hypotension have included chronic renal failure, gangrene, and telogen effluvium.[85,163,206,262,266] Other sequelae, such as neuropsychological abnormalities, prolonged myalgia and weakness, carpal tunnel syndrome, chronic dermatitis, Raynaud syndrome, and new allergies are explained less easily. Impaired memory and concentration have been found in patients who did not require any therapy other than intravenous fluids to restore their blood pressure.[262] In one center, patients with nonmenstrual TSS had more serious short- and long-term neuropsychological complications than did patients with menstrual TSS.[163] Sequelae related primarily to the neuromuscular system have resulted in speculation that the TSS-associated toxin may have a direct effect on nerve or muscle tissue.

One study compared the sequelae in 183 women with TSS and 366 control women hospitalized for appendicitis and appendectomy and matched for age, race, and duration of follow-up.[85] In contrast to controls, women with TSS were significantly more likely to report sequelae involving fatigue, hair loss and nail changes, problems with concentration and memory loss, emotional changes, and multiple organ systems (conditions involving the joint, cardiac, muscle, and genitourinary systems). Fertility patterns and pregnancy outcomes were similar in controls and women with TSS, both before and after the index illness.[85]

Recurrences

TSS carries a high rate of recurrence in patients with inadequately treated disease.* A small number of patients with menstrual disease and repeated tampon exposure have experienced as many as 6 to 12 recurrences. Recurrences associated with menstrual disease have no predictable pattern. In most patients the first episode is the most severe. However, asymptomatic menses may occur between symptomatic episodes, and the most severe episode may occur after one or more milder episodes.[84] Antistaphylococcal antimicrobial therapy for 10 to 14 days and discontinuation of tampon use reduces the rate of recurrence significantly.[84] Recurrences after nonmenstrual TSS are well described and usually are associated with inadequate initial therapy.[6,163,238]

The absent or delayed antibody response to TSST-I found in both menstrual and nonmenstrual TSS patients probably accounts for the continued susceptibility to TSS and high recurrence rate.* The fact that superantigenic toxins are not processed by antigen-processing cells and T lymphocytes as conventional antigens may provide an explanation for the poor convalescent antibody response to these antigens.[170]

Culture-negative, menses-associated recurrent episodes of TSS continue to be found in a small number of patients despite discontinuation of tampon use and administration of appropriate antimicrobial therapy during the acute episode.[84] Administration of an oral β-lactamase–resistant antistaphylococcal antimicrobial agent during menses has been tried in an attempt to prevent these recurrences but is not always successful. In recurrent cases resistant to this form of prophylaxis, consideration could be given to the untested and empirical use of rifampin, clindamycin, erythromycin, or IVIG (if the patient has no antibody to TSST-I) or to the use of an oral contraceptive.[195]

Atypical Manifestations

Mild Disease

Recognition of mild episodes of TSS is particularly important in patients with menstrual TSS because repeated use of tampons and the risk for recurrence are episodic.[56,92,310] Patients with mild or severe menstrual TSS typically do not form antibody to TSST-I during convalescence[21,30,263,283,325] and, without appropriate therapy, may have one or more recurrences. Such recurrences may be mild or severe.[83,84,196] Patients with nonmenstrual TSS also do not form antibodies in convalescence. A mild episode may be recognized only in retrospect, after desquamation, a recurrent episode, or both develop.[238]

The presence of any combination of fever, headache, sore throat, diarrhea, vomiting, orthostatic dizziness, syncope, and myalgia in a menstruating woman or an individual with a potential *S. aureus* infection should raise suspicion of TSS. A positive culture for *S. aureus* is helpful but not diagnostic because *S. aureus* may be cultured from the cervix or vagina in up to 33 percent of menstruating women.[190,245] Other laboratory data usually do not reflect multisystem involvement in mild disease, and assays for TSST-I in body fluids are investigational.[199,316] Support for the diagnosis of mild TSS depends on the

*References 6, 55, 83, 84, 195, 296.

*References 21, 30, 186, 263, 283, 296, 325.

constellation of findings present, including subsequent desquamation of the palms, soles, toes, or fingers; demonstration that *S. aureus* isolates from the site of infection produce TSST-I or an enterotoxin; absence of antibody to TSST-I or enterotoxins in acute-phase serum; and recurrent disease, if it develops.

Nonmenstrual Disease

The incidence of postoperative cases of TSS after all types of surgery has been estimated to be 3/100,000 population.[136] For ear, nose, and throat surgery, the incidence is higher (16.5/100,000 population).[157] A striking feature of most postoperative cases with rapid onset is the absence of any signs of wound infection.[17,136,251,264] The mean time from surgery to the onset of symptoms is 2 to 4 days.[17] Nosocomial acquisition of TSST-I–positive organisms rarely has been documented for postoperative cases.[9,164,207] A wide variety of types of surgery have been associated with TSS.*

Burn wounds provide a particularly rich environment for growth of *S. aureus* and the production of toxins.† In burn centers, TSS occurs predominantly in young children with small burns.[106] In one large pediatric burn center, *S. aureus* normally was not cultured from any site on admission.[59] However, it was acquired within a few days of admission and became the most common wound pathogen. Of all wound isolates of *S. aureus*, just 16 percent produced TSST-I. Only 50 percent of the children had antibodies to TSST-I on admission, which reflects the low prevalence of antibodies in this population.[317] Of blood products administered, 76 percent had antibodies to TSST-I, and seroconversion occurred in children receiving these products. A toxic shock–like syndrome developed in 13 percent (7/53) of children, only one of whom had TSST-I–producing *S. aureus* isolated from the wound. Staphylococcal enterotoxins A and B were produced by isolates from three patients. In burn patients, issues regarding the use of prophylactic antibiotics and occlusive dressings and enhancement of TSST-I production by topical antimicrobial agents are unsettled.[105] The mortality rate associated with TSS in children with burns may be as high as 57 percent.[127] Skin disrupted in any way, including disruption by varicella or a tattoo, also may be a focus for TSS.[21,34,70]

Patients whose anterior nares have been colonized by *S. aureus* are at particular risk for the development of TSS when the respiratory mucosa is disrupted by surgery, trauma, or a respiratory tract infection such as influenza.[21,47,69,185,312] TSS has been reported in association with sinusitis,[21,116] pharyngitis,[21,267] parapharyngeal abscesses,[267] tracheitis,[21,76,99,130,222] pneumonia,[21,79] rubeola,[298] and submandibular space abscesses. TSS occurring after ear, nose, and throat surgery has been associated with the use of nasal splints and packing materials and in part may be the result of interruption of the ciliary blanket.[3,21,126,211,332]

After orthopedic procedures or in association with bone and joint infections, the clinical manifestation of TSS may be confusing as a result of the intense and generalized myalgias associated with TSS, which may be misinterpreted as postoperative musculoskeletal symptoms. The wounds usually appear to be benign.[21,210,246,302] Infected abrasions under casts may be focal sites of TSST-I production.[287]

In one center, when cases of nonmenstrual TSS were compared with menstrual cases, patients with nonmenstrual disease were found to have a delayed onset of symptoms after the precipitating event, more frequent central nervous system manifestations, less frequent musculoskeletal involvement (myalgia and arthralgia), and a higher degree of anemia.[163] Recurrences occurred in both groups in untreated patients, and mortality rates were not different. Clinical differences between the two categories may be related to differences in the types of toxins produced. TSST-I was produced with comparable frequency in both groups. Staphylococcal enterotoxin A was produced less often by nonmenstrual isolates, and menstrual isolates more often produced both TSST-I and staphylococcal enterotoxin A. Staphylococcal enterotoxin B was produced more frequently by nonmenstrual isolates.

Recalcitrant Erythematous Desquamating Disorder

An atypical, subacute variant of TSS has been described in patients with acquired immunodeficiency syndrome (AIDS) and labeled recalcitrant erythematous desquamating disorder. *S. aureus* strains producing TSST-I or staphylococcal enterotoxins A or B have been isolated from patients with AIDS and prolonged erythema, extensive cutaneous desquamation, hypotension, tachycardia, and multiple and variable organ involvement.[67,98,169] The illness is recalcitrant, prolonged, and characterized by multiple recurrences. In one patient, elevated levels of TNF and IL-6 were found during severe episodes. When antitoxin antibodies have been measured during recurrence, they have been undetectable. Two patients responded well to IVIG.[67,169] Patients with the combined cellular and humoral immunodeficiencies of AIDS may be at particular risk for the development of severe, frequent, and prolonged recurrent episodes of TSS.[67,98,119,169,286] TSST-I and the enterotoxins may activate human immunodeficiency virus type 1 (HIV-1) gene expression in vivo, as has been observed in vitro.[128]

Neonatal Toxic Shock Syndrome–Like Exanthematous Disease

A toxic shock–like illness related to TSST-1–producing MRSA, neonatal toxic shock syndrome–like exanthematous disease (NTED), was initially described in neonates in Japan[300] and subsequently recognized in France.[315] These infants present in the first week of life with a combination of a generalized erythematous macular rash, thrombocytopenia, elevated acute-phase reactants, and fever. Patients are colonized with MRSA of a single clonal type that produces TSST-I and staphylococcal enterotoxin C.[167] Although no focus of infection is present and no exotoxins are detectable in serum, analysis

*References 21, 40, 215, 228, 256, 281, 284, 313.

†References 11, 59, 66, 105, 127, 129, 133, 147, 188, 192, 321.

of T cells shows selective expansion of $V_\beta 2$-positive T cells during the acute phase as a result of selective activation of TSST-I–reactive T cells.[299,300] Maternal IgG antibody to TSST-I plays a protective role in preventing NTED.[299] Although complications occur in premature neonates, term infants typically recover within 5 days without active treatment. The limited disease in contrast to TSS has been attributed to the minute amount of exotoxin from colonized sites and the high susceptibility to induction of anergy in the immature T cells of neonates.[299,300]

Streptococcal Toxic Shock Syndrome

An increase in the incidence and severity of *S. pyogenes* was recognized in the 1980s. These infections included septicemia, necrotizing fasciitis, and a streptococcal toxic shock–like syndrome. In 1993, the Working Group on Severe Streptococcal Infections proposed a consensus definition for streptococcal TSS with clinical criteria, including isolation of group A streptococci from a normally sterile site, hypotension, and two or more of the following: renal impairment, coagulopathy, liver dysfunction, acute respiratory distress syndrome, erythematous macular rash, and soft tissue necrosis.[329]

Since the 1990s, the rate of severe streptococcal infections has stabilized to 2 to 4 cases/100,000 per year. In adults, streptococcal TSS comprises 10 to 15 percent of severe streptococcal infections, with a mortality rate of 30 to 70 percent.[80,91,178] Streptococcal TSS is rare in children and carries a lower mortality rate than in adults. A multicenter study covering a U.S. population of 29.7 million from 2000 to 2004 identified 5400 cases of invasive group A streptococcal infection (3.5/100,000 per year), including 572 children younger than 10 years of age. Of the 572 children with severe streptococcal infection, 26 (4.6%) developed streptococcal TSS with a 7.2 percent case-fatality rate. [227]

Streptococcal TSS is similar to staphylococcal TSS in that it is mediated by superantigenic toxins and results in endothelial damage, hypotension, and multisystem organ involvement. It differs from staphylococcal TSS in numerous respects, including a slower onset over the course of several days; usual absence of vomiting, profuse diarrhea, and conjunctival infection; frequent absence of erythroderma or the presence of only a sandpaper-like rash; severe generalized hyperesthesia; and extreme pain at the site of skin involvement.[68,290,292] Both cell-associated and soluble streptococcal virulence factors, including M protein and pyrogenic exotoxins A and B, have been implicated as superantigens mediating the systemic effects of streptococcal TSS.[36,110,146]

Treatment follows the same principles as for staphylococcal TSS: identification of the focus of toxin production, identification and susceptibility testing of the organism, administration of antibiotic therapy to block synthesis of the toxin and to kill *S. pyogenes*, and management of the systemic multiorgan actions of the toxins. Although penicillin is the drug of choice for treatment of most group A streptococcal infections, the addition of clindamycin to inhibit protein synthesis is beneficial in cases of streptococcal TSS.[290]

IVIG as adjunctive therapy for streptococcal TSS has been supported by in vitro studies[258] and case reports in humans,[16,37,219,331] but clinical studies have been inconclusive. Downregulation of the lymphokine production induced by streptococcal pyrogenic exotoxin A by IVIG has been demonstrated in vitro.[219,283] A multicenter, randomized, double-blind, placebo-controlled trial to study IVIG for streptococcal TSS in adults showed 3.6-fold higher mortality in the placebo group. However, statistical significance was not achieved because the study identified only 10 IVIG recipients and 11 placebo patients before premature termination because of slow patient recruitment.[77] A multicenter, retrospective cohort study of children with streptococcal TSS from 2003 to 2007 identified 192 cases divided into 84 IVIG recipients and 108 nonrecipients. The study found no statistical difference in length of hospital stay or mortality, but there were only 3 deaths in either group.[279] As with staphylococcal TSS, experts recommend that IVIG be considered for cases of streptococcal TSS that are refractory to aggressive therapy or for patients with an inaccessible focus of infection.

Several patients with TSS have been reported to be simultaneously infected with *S. aureus* and *S. pyogenes*.[107] Determining which infection primarily was responsible for the manifestations or whether an amplified effect of exotoxins from both organisms was present was not possible.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of TSS includes clinical entities in which a rapid onset of fever, erythroderma-like rash, hypotension, and multisystem involvement are observed (Table 64-4).*

PREVENTION AND PROPHYLAXIS

To decrease the risk for development of menstrual TSS, in 1982, the Institute of Medicine Committee on TSS recommended that women, particularly adolescents, minimize their use of high-absorbency tampons.[154] The committee also recommended that women who have had TSS not use tampons. Although the frequency of changing tampons has not been associated with risk for TSS, limiting individual tampon use to less than 12 hours might decrease the risk for menstrual TSS. Women using intravaginal contraceptive devices also should be informed of the potential increase in risk for development of TSS.[277]

Although postoperative TSS is a rare event, it generally occurs in healthy people. As a result of the unexpected and potentially severe consequences of TSS, issues regarding surgical antimicrobial prophylaxis for prevention have been raised. Perioperative systemic antistaphylococcal antibiotics did not prevent TSS in four patients[32,264] and do not eradicate nasal carriage of *S. aureus*.[159] TSS with onset after 48 hours of amoxicillin

therapy was reported in two patients after endonasal sinus surgery.[2] Topical bacitracin ointment on nasal packing does not prevent the development of TSS.[32,93,157,159]

Most authors contend that the rare risk for development of postoperative TSS is comparable to the risk for having a severe antimicrobial reaction and that perioperative antimicrobial prophylaxis is not indicated for clean procedures of short duration.[136,251] Effort should be intensified to recognize postoperative cases early; to open, explore extensively, and irrigate wounds; and to provide immediate antimicrobial and supportive therapy for suspected TSS.

CHARACTERISTICS OF TOXIC SHOCK SYNDROME–ASSOCIATED *STAPHYLOCOCCUS AUREUS* ISOLATES

The ability to produce TSST-I, a previously uncharacterized protein, is the single most distinguishing characteristic of TSS-associated *S. aureus* strains. More than 90 percent of *S. aureus* isolates from patients with menstrual TSS[22,273] and 40 to 60 percent of isolates from patients with nonmenstrual disease[131] produce TSST-I, in contrast to less than 20 percent of non-TSS strains. *S. aureus* strains isolated from patients with TSS are phenotypically different from other strains of *S. aureus*.[21,306] They produce less β-hemolysis on sheep blood agar and less frequently harbor plasmids. Next to TSST-I production, production of protease is the most characteristic marker for these strains.[306] Unlike non-TSS *S. aureus* strains, most TSST-I–positive strains of *S. aureus* require tryptophan for growth and production.[64] Additional differences between TSS and non-TSS strains of *S. aureus* include the resistance of TSS strains to cadmium, arsenate, and penicillin, characteristics that usually are plasmid mediated but, in TSS strains, are chromosomally mediated.[21,306] TSST-I production is unrelated to methicillin susceptibility or resistance.[274]

ROLE OF STAPHYLOCOCCAL EXOTOXIN TOXIC SHOCK SYNDROME TOXIN–I AND THE ENTEROTOXINS IN TOXIC SHOCK SYNDROME

Role of Toxic Shock Syndrome Toxin–I

TSST-I appears to be an important toxin in TSS. Factors supporting this statement include (1) the observation that more than 90 percent of isolates from patients with TSS produce TSST-I, (2) the absence of acute-phase antibody to TSST-I in more than 90 percent of patients with menstrual TSS, (3) the increase in anti–TSST-I antibody during recovery in nonmenstrual cases, (4) absent or low levels of antibody in patients with recurrent menstrual TSS, (5) comparable illness inducible with TSST-I in in vivo animal models, and (6) neutralization of IL-1 stimulation and response to TSST-I by antibody to TSST-I.

Most convincing are experiments in which the ability to cause TSS followed bacteriophage-mediated transfer of the TSST-I–positive chromosomal segment into a recipient *S. aureus* strain without the segment.[88,238] Experiments demonstrating the effectiveness of monoclonal antibodies to TSST-I in reversing the effects of TSST-I provide additional strong support.[175]

Role of Enterotoxins

Because 40 to 60 percent of nonmenstrual TSS *S. aureus* isolates and 5 to 10 percent of menstrual TSS isolates do not produce TSST-I, a role for other staphylococcal exotoxins, including the enterotoxins, has been proposed.* Patients with nonmenstrual disease infected with TSST-I–negative strains may have a higher mortality rate.[131] Significant increases in the titer of antibody to the staphylococcal enterotoxins during convalescence strongly suggest a role for these proteins in the pathogenesis of TSS.[12]

In rabbit models, the morbidity and mortality occurring after the injection of TSST-I–negative TSS isolates

*References 21, 71, 182, 194, 239, 269, 330.

were comparable to those occurring after infection with TSST-I–positive strains and significantly greater than after inoculation with TSST-I–negative non-TSS isolates.[131] Administration of staphylococcal enterotoxins to animals results in many of the manifestations characteristic of TSS.[20,109]

On examination of isolates from patients with TSS, production of TSST-I alone is the most common toxin pattern.[21,71,189] Other patterns include production of TSST-I in combination with one or more of the identified enterotoxins, production of enterotoxins *only* (one or more), and nonproduction of TSST-I and enterotoxins. Of the TSS strains producing TSST-I, 60.6 percent also produce an enterotoxin.[71,189] A clone producing both TSST-I and staphylococcal enterotoxin A is associated with 88 percent of menstrual TSS cases and up to 54 percent of isolates from nonmenstrual TSS cases.[51] TSST-I and staphylococcal enterotoxin A have a common major histocompatibility complex (MHC) class II binding domain and share overlapping domains critical for superantigenic activities. A monoclonal antibody to TSST-I inhibits these staphylococcal enterotoxin A–induced activities.[176] The third most common pattern of toxin production is that of TSST-I plus staphylococcal enterotoxin C. These isolates have been associated with both menstrual and nonmenstrual cases and particularly with severe respiratory tract TSS-associated infections.[71] The fourth pattern is that of staphylococcal enterotoxin B alone. In one study, strains producing staphylococcal enterotoxin B alone accounted for 38 percent of all nonmenstrual TSS isolates.[182,269] This prevalence is significantly higher than that for isolates from non-TSS *S. aureus* infections (15%) or asymptomatic carriers (13%). Staphylococcal enterotoxin B never is coexpressed with TSST-I.[89] A TSS isolate producing no known toxins is the least common pattern. The identification of new enterotoxins[255,297] capable of producing TSS-like disease in rabbits may account for isolates previously identified as producing no toxins.

PREVALENCE OF EXOTOXIN-PRODUCING *STAPHYLOCOCCUS AUREUS* STRAINS AND ANTIBODY TO THE EXOTOXINS

Prevalence of Exotoxin-Producing Organisms

TSST-I–positive strains of *S. aureus* have been present since at least 1957, and antibody to TSST-I was as prevalent in the general population in 1960 as it was in 1999.[243,317] Thus, the increase in incidence of TSS from 1980 to 1985 is assumed to have been the result of newly introduced cofactors rather than an increase in the prevalence of TSST-I–positive organisms.

S. aureus is present in 20 to 40 percent of cultures from the anterior nasal vestibule of adults and in as many as 33 percent of nasal cultures from children.[156] A study of 3012 menstruating women between 13 and 40 years of age in North America from 1998 to 1999 showed that 26 percent were colonized with *S. aureus* in at least one of three body sites (nose, vagina, or anus) and 9 percent were colonized vaginally.[243] In women, the prevalence of *S. aureus* in vaginal cultures is higher during menses than at midcycle.[190,230] Vaginal carriage rates vary from 7 percent in premenarcheal and nonmenstruating women to 33 percent in menstruating women.[243,245] TSST-I–positive *S. aureus* is present in 1 to 5 percent of vaginal cultures in women, 7 percent of nasal cultures in hospitalized patients, and 18 percent of nasal cultures in children. In prospective studies of *S. aureus* isolates from healthy individuals and from specimens received for other purposes, 14 to 39 percent of all isolates produced TSST-I and 7 to 14 percent produced staphylococcal enterotoxin B.[92,238,243] Overall, between 1 and 7 percent of healthy individuals at any given time are colonized at a mucosal site with TSST-I–positive *S. aureus*.

Of 60 *S. aureus* isolates from blood cultures of patients who did not have TSS, 28 percent produced TSST-I.[54] Presumably, these patients had circulating antibody to TSST-I that prevented the development of TSS despite *S. aureus* infection. Adults and children with persistent nasal carriage of a TSST-I–positive strain have high levels of antibody to TSST-I.[243,258]

Evidence suggests that a single clone of *S. aureus* causes most cases of TSS.[51,218] Multilocus enzyme electrophoresis has demonstrated that the TSST-I gene *tst*H is distributed widely over the whole spectrum of *S. aureus* genotypes. Of 315 *S. aureus* strains collected from around the world, 88 percent of menstrual TSS strains and 53 percent of nonmenstrual strains were indistinguishable by multilocus enzyme electrophoresis. The same clone also was found in 28 percent of vaginal isolates from asymptomatic women. This phenomenon may reflect the unique ability of this clone to colonize the urogenital epithelium or the unique capability of this clone to cause disease. Although TSS strains are similar in gene content, indicative of a common ancestor, their considerable heterogeneity indicates that the common ancestor was not recent in evolutionary time.[124] Thus, the TSS outbreak was the result of a change in the host environment and not geographic dissemination of a new "hypervirulent" strain.[124]

Even though TSST-I–positive strains may cluster within families, living units, and hospital settings, the occurrence of TSS clusters is a rare event.[173,216] Probable TSS has developed within 24 hours in a husband and wife[121] and in two mother–daughter pairs. Nosocomial acquisition and transmission of TSST-I–positive organisms have been described.[9,173,216]

Prevalence of Antibody to Exotoxins

Antibody formation to exotoxins is thought to result from mucosal colonization with TSST-I–positive *S. aureus* strains.[9,258] Antibody titers were higher in women colonized with toxigenic *S. aureus* whether the colonization was persistent or transient.[244] Subclinical and mild, unrecognized disease may result in the formation of antibodies as well.[56] Patients in whom TSS develops have significantly lower levels of antibody to TSST-I and staphylococcal enterotoxins B and C than the general

population.[21,71] The antibody response to TSST-I is absent or delayed in both menstrual and nonmenstrual TSS.[238,296]

The prevalence of antibody to staphylococcal exotoxins increases with age. Antibody to TSST-I in 689 Wisconsin residents was found to be 47 percent at 1 year of age, 58 percent at 5 years, 70 percent at 10 years, 88 percent at 20 years, and 96 percent for ages 30 to 50 during the years 1960 to 1983 (see Fig. 64-2).[42] A study of 3012 menstruating women between 13 and 40 years of age across North America in 1998 and 1999 found similar results, with 85 percent overall and 81 percent of subjects aged 13 to 18 years having positive antibody to TSST-I.[243] The presence of transplacental antibody in more than 90 percent of infants also was demonstrated.[317] For enterotoxins, by the time that children reach 10 years of age, the proportion with antibody titers of 1:100 or higher is 15 percent for staphylococcal enterotoxin A, 65 percent for staphylococcal enterotoxin B, 30 percent for staphylococcal enterotoxin C, 5 percent for staphylococcal enterotoxin D, and 20 percent for staphylococcal enterotoxin E. By 22 years of age, the numbers increase to 55 percent for staphylococcal enterotoxin A, 77 percent for staphylococcal enterotoxin B, and 98 percent for staphylococcal enterotoxin C.[21]

Racial, sexual, and geographic differences in antibody prevalence have been noted. Among carriers of toxigenic *S. aureus*, a lower percentage of black women (89%) than white or Hispanic women (98% and 100%, respectively) had positive antibody titers. Sera randomly selected from 87 control women were seronegative more frequently for antibody to TSST-I (24%) than were those from 66 control men (9%), which led to the suggestion that women may be more susceptible than men to TSS.[263] A 2003 multicenter study of 3012 women from Ohio, New Jersey, Florida, Arizona, and Manitoba, Canada, found the prevalence of positive antibody to TSST-I (titer of ≥1:32) to be high in all geographic sites (82% to 89%). Although no regional differences were found in rates of *S. aureus* colonization, subjects from Manitoba were significantly more likely to have a positive antibody titer than were subjects from the other locations except Arizona.[243]

PHYSICOCHEMICAL AND BIOLOGIC CHARACTERISTICS OF TOXIC SHOCK SYNDROME TOXIN–I

Physicochemical Properties, Structure, and Function

Most bacterial superantigens are protease-, heat-, and acid-resistant, compact globular proteins of 20 to 30 kDa that share immunologic, biologic, and functional properties.[27] The mature secreted TSST-I protein is a single polypeptide chain with a molecular weight of 22,000 daltons. It is resistant to proteolytic digestion by trypsin but is hydrolyzed by pepsin at pH 4.5. In sterile solution at neutral pH, it is stable for months. TSST-I can be heated to 100° C (212° F) for longer than an hour without loss of biologic activity.[27] The molecule is folded into two closely associated domains that create two major grooves, the front and backside grooves, similar to the crystal structures of other superantigens.[193] Although they do not share sequence homology or obvious structural features, all of the secreted superantigens share a three-dimensional conformation that allows them to interact simultaneously with two different receptors on two different cell types.[27,170]

Efforts to understand the molecular actions of TSST-I have focused on separating regions that interact with the T-cell receptor from those required for lethality.[27,29,30,217] In animal models, lethality, induction of fever, and endotoxin susceptibility do not depend on T-cell proliferation as measured by superantigenic activity but must involve interaction of toxin with other host-cell receptors in the body.[27]

Regulation of Production

S. aureus is highly adaptable and able to live and grow in extremes of temperature, pH, and oxygen concentration. TSST-I production, however, is controlled tightly. TSST-I is not produced in unfavorable conditions, including an anaerobic environment, pH values lower than 6.0 or greater than 8.0, concentrations of clindamycin below the MIC of the organism, glucose concentrations greater than 3 percent, and temperatures lower than 37° C (98.6° F) or greater than 40° C (104° F).[21,27,308,328] The role of magnesium is unclear.[212]

Under optimal in vitro growth conditions, TSST-I production lags behind but parallels bacterial growth. Like other *S. aureus* exotoxins, TSST-I is made primarily during the postexponential phase of growth, when nutrients are scarce and cell density is great.[92] Levels of TSST-I remain stable throughout the stationary phase, even after the organisms begin to die. Under less than optimal conditions, synchronous production of TSST-I and growth of *S. aureus* do not occur. For example, clindamycin at concentrations below the MIC for the organism will inhibit the production of toxins without altering growth.[271]

The gene *tst*H is encoded by a transposon-like mobile genetic element.[64,89,152,174] The chromosomal fragment with the structural gene for production of TSST-I is a 10.6-kilobase (kb) unit that has been cloned in *E. coli*. *tst*H has been sequenced and encodes a 234–amino acid protein that is converted by the removal of a signal peptide of 40 amino acids to the mature exotoxin of 194 amino acids.[27,92,174] Production of TSST-I and other post–exponential-phase virulence factors is regulated by three separate genetic loci: the accessory gene regulator *(agr)*, the staphylococcal accessory regulator *(sar)*, and the extracellular protein regulator *(xpr)*.[12,27,92] All three regulators affect gene expression at the level of transcription during the late log phase of bacterial growth.

Glyceryl monolaurate, a surfactant and emulsifier used in food and cosmetic industries, inhibits the production of staphylococcal and streptococcal exotoxins at concentrations subinhibitory to growth.[250,270] As a lipophilic compound, the mechanism of action appears to be insertion into the cell membrane, with resulting interruption of signal transduction. Other surfactants used in the

tampon industry have been found to both inhibit and enhance[272] the production of TSST-I in vitro.

Kinetics of Distribution

Detecting TSST-I in body fluids is difficult. In humans, nanogram quantities have been detected by radioimmunoassay in the breast milk of a woman with TSS,[153,316] in serum early during illness in two of four patients,[199] in urine, and in vaginal washings in a small number of patients.[199] By means of the rabbit subcutaneous wiffle ball abscess model, TSST-I can be detected first in abscess fluid 4 hours after *S. aureus* has been inoculated into the wiffle ball and in urine 48 hours after inoculation.[199] When TSST-I radiolabeled with iodine-139 was injected intravenously into rabbits, measurement of plasma clearance demonstrated a half-life of 1.5 hours. Within 15 minutes of injection, TSST-I was concentrated fourfold in blood cells in contrast to plasma. Toxin persisted in the cellular compartment, and plasma concentrations fell. After 3 hours, most of the radiolabel was found in the spleen. TSST-I and staphylococcal enterotoxins A and B can cross epithelial membranes intact in a fully functional form.[139] In a cellular model of the blood-brain barrier, TSST-1 showed slow bidirectional movement consistent with restricted paracellular diffusion.[18]

Cellular Interactions

TSST-I has been shown to inhibit systolic function in isolated rabbit atria.[229] It also can bind directly to human and porcine endothelial cells and is cytotoxic to porcine endothelial cells because it permits leakage across endothelial cell monolayers.[177,181] However, concentrations of TSST-I needed to induce these and other diverse cytotoxic changes in vitro are higher than the usual tissue and serum levels. Interactions of TSST-I and the enterotoxins with T lymphocytes and antigen-processing cells are described in the next section.

Biologic Functions

Much information regarding pathogenesis has been obtained from the subcutaneous wiffle ball and vaginal tampon rabbit models and a primate model.[87,237] Rabbits and baboons exhibit clinical and laboratory changes most consistent with the human syndrome, including lethality.* The signs and symptoms observed in these animals after the intravenous injection of purified TSST-I include skin erythema, conjunctivitis, diarrhea, lethargy, tachypnea, respiratory distress, central nervous system changes, and increased capillary permeability.

The absence of in vitro cytotoxicity of TSST-I[21,237] despite potent in vivo biologic effects suggests an important role for endogenous mediators in TSS. The ability of staphylococcal enterotoxin B to induce dramatic T-cell proliferation was recognized a decade ago.[165,170] Subsequent work has shown it to be a feature of other bacterial exotoxins, including TSST-I, the staphylococcal enterotoxins, the streptococcal pyrogenic exotoxins A and C, a new streptococcal superantigen, and a streptococcal M surface protein.[170] The term *superantigen* was coined in 1989 to describe antigens that at concentrations lower than those of conventional antigens (picomolar concentrations) can stimulate proliferation of a large percentage of T cells bearing a T-cell receptor β-chain variable (V_β). Such activation of T cells results in profound alterations in immune system homeostasis by inducing the release of large quantities of monokines (IL-1, TNF-α) and lymphokines (IL-2, TNF-β).[170,282,334]

T cells are activated to produce lymphokines as a result of T-cell receptor–antigen binding and activation of signal transduction.[52,101,289] Antigens can bind to the T-cell receptor as conventional antigens or superantigens. Conventional antigens enter antigen-processing cells by endocytosis. They are broken into small peptides and form complexes with one of the allele-restricted MHC class II molecules.[282] This complex is transported to the cell surface, where it is recognized by a specific T-cell receptor. T-cell receptor gene rearrangement gives more than 10,000 possible combinations to recognize conventional antigenic peptides presented by antigen-processing cells.[282] Thus, one peptide will activate only 1 in 10^4 to 10^6 T cells, and only $CD4^+$ T cells respond to conventional antigens.

Superantigens are presented to T lymphocytes in a very different fashion. They bind as intact proteins to most allelic forms of MHC class II molecules in an unrestricted fashion at a site outside the peptide-binding groove. They then react with the T-cell receptor through the V_β element and will react with all T cells carrying that V_β element.[150] Because only 25 to 50 major families of V_β genes exist in humans, each superantigen can interact with 5 to 20 percent of resting T cells, depending on the frequency of T cells expressing that V_β family in each individual's repertoire. Both $CD4^+$ and $CD8^+$ T cells are activated. The fact that superantigens bind only to selected and specific V_β elements distinguishes them from the nondiscriminating mitogens.

Once the T cell has recognized the superantigen,[137] both antigen-processing cell and T-cell activation by signal transduction[52] result in release of cytokine by the antigen-processing cell (IL-1, TNF-α) and the lymphocyte (IL-2, TNF-β). In mice and possibly also in humans, the initial T-cell activation occurs in lymph nodes.[209] Within hours of T-cell activation by superantigens, cytokines are detected in vitro and in serum in vivo.

TSST-I binds only to the $V_\beta 2$ element.[260] In humans with TSS caused by TSST-I–secreting *S. aureus*, within 10 to 14 days 30 to 70 percent of the circulating T-cell population will be T cells bearing the $V_\beta 2$ element.[60,61,191] The number of circulating $V_\beta 2$ T cells does not return to normal for several months. In contrast, patients with TSS caused by *S. pyogenes* have a consistent pattern of depletion of certain V_β T-cell types after T-cell activation.[170,224,320] In mice, such depletion is thought to be the result of programmed cell death (apoptosis).[207,208] Thus, activation of T cells by superantigens may result in massive cytokine release with subsequent selected V_β T-cell expansion, T-cell deletion, or apoptosis, depending on the superantigen and species.

*References 29, 87, 88, 200, 203, 239, 252, 273, 278.

Evidence from the mouse model supports a central role for T-lymphocyte activation in superantigen-mediated disease. Mice that have received cyclosporine to block T-cell activation and lymphokine production or mice with severe combined immunodeficiency disease are protected against staphylococcal enterotoxin B–induced lethal shock. Repopulation with T cells results in susceptibility to staphylococcal enterotoxin B. The same mice are not protected against endotoxin-induced shock because lipopolysaccharide activates only monocytes.[207-209] Mononuclear production of IL-1 and TNF-α is central to the shock induced by an endotoxin. Production of these two cytokines in addition to production of the lymphokines IL-2, IFN-α, and TNF-β may explain the enhanced severity of superantigen-associated TSS.[28,137,170] If more than one superantigen is produced by an organism, different V_β specificities would result in an even greater number of T cells being activated, with the potential for development of disease with enhanced severity and mortality.

Once superantigens have resulted in monokine and lymphokine release, the subsequent pathophysiologic events appear to be related to the many and complex interactions of these cytokines,[28,141,333] with the ultimate result being profound endothelial damage. TNF-α and TNF-β and the complex interaction of cytokines, leukotrienes, prostaglandins, adhesion molecules, nitric oxide, platelet-activating factor, complement components, neutrophils, platelets, and endothelium-derived factors appear to be responsible for the extensive endothelial damage and resulting capillary fluid leakage and the decrease in peripheral vascular resistance.[28,141,265,333]

CHAPTER 65

Acute Respiratory Distress Syndrome in Children

Jan Hau Lee • Ira M. Cheifetz • David A. Turner

Acute respiratory distress syndrome (ARDS) is characterized by severe hypoxemia and diffuse infiltrates on radiologic examination. ARDS represents the final common pathway and clinical presentation of the most severe acute lung injury (ALI), which may be precipitated by various pulmonary (direct) or nonpulmonary (indirect) insults. Infections are an important cause of ARDS in children, with pneumonia and sepsis being most common.[39,116] ARDS is an important consideration in the setting of pediatric infectious disease, given the wide range of infections that may lead to this complication and its associated morbidity and mortality.[39,116] Morbidity, mortality, and resource usage related to ARDS also increase during outbreaks of infectious diseases, as seen during the 2009 to 2010 global influenza H1N1 pandemic.[36,87] This chapter will discuss the definition, pathophysiology, presentation, and clinical management of critically ill children with ARDS, with an emphasis on aspects that may be of particular interest to pediatric infectious disease specialists.

TABLE 65-1 The Berlin Definition of Acute Respiratory Distress Syndrome 2011

	Acute Respiratory Distress Syndrome		
Criteria	**Mild**	**Moderate**	**Severe**
Time of onset	Within 1 week of known clinical insult or new or worsening respiratory symptoms		
Degree of hypoxemia	P/F ratio 201-300 with PEEP/CPAP ≥5	P/F ratio ≤200 with PEEP ≥5	P/F ratio ≤100 with PEEP ≥5
Origin of edema	Risk factors for ARDS must be present. Respiratory failure that is not fully explained by cardiac failure or fluid overload.*		
Radiologic findings+ (CXR or CT scan)	Bilateral opacities that are not fully explained by effusions, lobar or lung collapse, or nodules		

*If no risk factors are present, objective measures (e.g., echocardiography) are required to exclude hydrostatic edema.
ARDS, Acute respiratory distress syndrome; *CPAP,* continuous positive airway pressure; *CT,* computed tomography *CXR,* chest radiography; *PEEP,* positive end-expiratory pressure.

DEFINITION

Although first described by Ashbaugh and colleagues in 1967,[11] no formal definition of ARDS was developed for over 25 years. In 1994, the American-European Consensus Conference (AECC) defined ARDS as follows[15]:

1. Acute onset of respiratory symptoms
2. Frontal chest radiograph with bilateral infiltrates
3. Partial pressure of oxygen (Pao_2) to fraction of inspired oxygen (Fio_2) ratio (P/F ratio) 200 mm Hg or less
4. No clinical evidence of left atrial hypertension as defined by a pulmonary capillary wedge pressure less than 18 mm Hg (if measured)

The AECC also designated the term *acute lung injury* as a part of the spectrum of ARDS, and ALI is defined by a P/F ratio between 201 and 300 mm Hg. Despite the limitations,[111] these formal definitions have allowed for standardization of terminology and led to landmark clinical studies in ALI and ARDS that have contributed to improved understanding of this spectrum of conditions over the past 18 years.[20,41,104]

Recently, the Berlin Definition of ARDS was proposed by the European Society of Intensive Care Medicine (ESICM) in collaboration with the American Thoracic Society (ATS) at the ESICM Congress in October, 2011.[35,105] This new definition proposes that the term *ALI* be removed and ARDS be considered a single entity with three subgroups based on severity of hypoxemia (i.e., mild, moderate, and severe). The Berlin Definition of ARDS takes into account the timing of onset, degree of respiratory support (positive airway pressure), and overall fluid status. This new definition also allows for the use of either computed tomography (CT) of the chest or standard chest radiograph for determination of ARDS (Table 65-1).

ETIOLOGY

Numerous insults that both directly and indirectly affect the lung can lead to generation of inflammatory mediators that contribute to development of ARDS (Table 65-2). Direct pulmonary insults include pneumonia, aspiration, chest trauma, near drowning, and smoke inhalation. Indirect lung injury may be the result of generalized systemic conditions, such as sepsis, closed head injury, multisystem trauma, transfusion reactions, pancreatitis, and hemorrhagic shock.

TABLE 65-2 Causes of Acute Respiratory Distress Syndrome

Direct (Pulmonary) Causes	Indirect (Nonpulmonary) Causes
Pneumonia Bacterial Viral – H1N1, RSV Mycobacterium Fungal	Severe sepsis and septic shock Multiple trauma Severe hemorrhage Severe pancreatitis Transfusion reaction
Aspiration	Cardiopulmonary bypass
Near-drowning	
Smoke or chemical inhalation	
Pulmonary contusion	
Fat embolism (rare in children)	

Infective etiologies account for a large proportion of the causes for ARDS, with bacterial and viral infections being the most common infectious etiologies of ARDS.[14] *Streptococcus pneumoniae* and *Pseudomonas aeruginosa* are common bacteria associated with severe pneumonia potentially leading to sepsis and, subsequently, ARDS.[14] Certain characteristics of these organisms have been shown to be instrumental in initiating this injury; for example, *P. aeruginosa* incites lung injury via the cytotoxic activity derived from the patatin-like phospholipase domain of ExoU toxin.[75]

Respiratory syncytial virus (RSV) infection is one of the most common indications for admission to the pediatric intensive care unit (PICU), especially during the winter months.[7] Although most critically ill children present as severe RSV bronchiolitis, a significant proportion (up to 27%) can present with ARDS; those with preexisting conditions are at the highest risk.[46] The influenza viruses are the most common cause of viral-induced ARDS, especially during an epidemic or pandemic.[36,87] Bacterial coinfection in patients with the severe pandemic

H1N1 viral infection has been shown to increase the need for mechanical ventilation, duration of intensive care unit (ICU) stay, and mortality.[90] Specifically, coinfection with methicillin-sensitive *Staphylococcus aureus* at admission was independently associated with almost a threefold increase in mortality.[90] There is a growing concern of community-acquired methicillin-resistant *S. aureus* (MRSA) infection leading to severe necrotizing pneumonia and ARDS, even with non-H1N1 influenza infection.[53,69,107] A less common cause of viral-induced ARDS is the coronavirus, such as the strain that caused the severe acute respiratory syndrome (SARS) in 2003 and affected adults more severely than children.[59,60]

In addition to bronchiolitis and pneumonia, severe sepsis is also a leading risk factor for ARDS in children.[117] In critically ill adults, sepsis is also associated with an approximately 40 percent risk for developing ARDS.[77] Multiorgan dysfunction and other illnesses associated with sepsis increase the risk for ARDS, and this risk is further compounded by the presence of chronic conditions or underlying comorbidities.[50] In addition, genetic differences, which regulate the immune responses of the lungs to these precipitating factors, account for differences in the degree of severity in ARDS in individual patients, even when similar risk profiles are present.[80] One such example of genetic polymorphisms is that related to nuclear factor-κB (NF-κB). Deletion polymorphism of the promoter region of this important transcription factor leads to inappropriate upregulation of proinflammatory genes, which has been shown to result in an increase in ARDS severity and mortality.[4,13]

Limited data exist on the impact of the underlying etiology of ARDS on clinical outcomes in children. In a study involving 736 adults with ARDS, patients with sepsis-related ARDS were more likely to have diabetes, longer pre-ICU stay, and higher APACHE III (a measure of severity of illness in critically ill adults) scores in contrast to those who had non–sepsis-related ARDS.[97] However, after accounting for differences in clinical characteristics, no difference was found in 60-day mortality between patients with sepsis-related ARDS and non–sepsis-related ARDS. Furthermore, no evidence exists to suggest that the source of sepsis is an important determinant of mortality in ARDS.[96]

INCIDENCE

In contrast to the incidence in adults, the incidence of ARDS in critically ill children is not as well described but does appear to be lower.[106] In a study conducted in the United States, 13 percent (828/6235) of patients who required mechanical ventilation had ARDS. This investigation reported an incidence of 16/100,000 person-years for those 15 to 19 years old and 306/100,000 person-years for adults 75 to 84 years old.[94] In a follow-up study involving children younger than 18 years, the incidence was 12.8/100,000 person-years.[117] Single-institution studies previously reported that ARDS accounted for 2.7 to 4.3 percent of PICU admissions.[28,43] In more recent data involving multiple centers, ARDS accounted for lower percentages (1.4% to 2.7%) of all PICU admissions,[49,116] making the conduct of clinical ARDS trials in critically ill children particularly challenging.

CLINICAL COURSE

The initial clinical course of ARDS begins with direct or indirect acute injury to the pulmonary parenchyma. In the initial stage, the clinical symptoms and physical findings vary depending on the etiology of the ALI. Children with pulmonary etiologies of ARDS will have predominantly respiratory symptoms; those with nonpulmonary etiologies of ARDS will have symptoms related to the initial insult (e.g., acute abdomen for pancreatitis). Early in the course of lung injury, patients may display mild tachypnea and dyspnea but tend to have normal radiographic findings.

After the inciting event and initial phase, a latent period follows that may last for a variable period. During this latent period, the patient may appear to be clinically stable, but early signs of pulmonary insufficiency develop, as manifested by hyperventilation with hypocarbia and respiratory alkalosis. The chest radiograph may remain clear or may begin to demonstrate a fine reticular pattern related to the development of pulmonary interstitial fluid (Fig. 65-1).[33] With progression of the lung injury, acute respiratory failure follows and is characterized by rapid onset of hypoxemia that is often refractory to supplemental oxygen administration. Diffuse pulmonary edema and worsening compliance cause significant atelectasis and intrapulmonary shunting. Clinically, patients develop rapid, shallow tachypnea with increased work of breathing. The physical signs of respiratory failure will vary with age and severity of illness, but usually include subcostal and supraclavicular retractions, grunting, and nasal flaring. Lung examination usually reveals diffuse crackles on auscultation. Radiographically, bilateral areas of consolidation with air bronchograms reflect alveolar filling and atelectasis (Fig. 65-2). A significant percentage of these children will require endotracheal intubation and

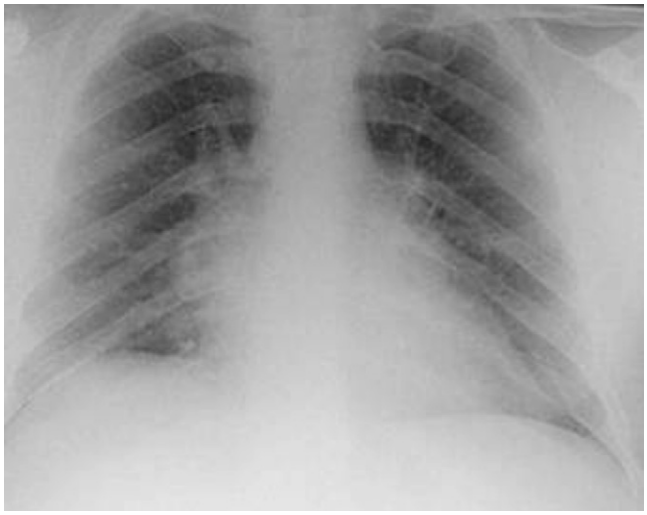

FIGURE 65-1 ■ Early stage of acute respiratory distress syndrome.

FIGURE 65-2 ■ Established acute respiratory distress syndrome.

mechanical ventilation with the application of positive end-expiratory pressure (PEEP). However, noninvasive ventilation may be an alternative for a subgroup of patients.[81]

Mortality

Most studies indicate that mortality associated with ARDS is due to nonrespiratory causes.[38,68] In most cases, early death (i.e., within 72 hours) is caused by the underlying illness or injury, whereas late death (i.e., beyond 72 hours) is caused by infection or multiorgan system failure. Reported mortality rates for children with ARDS vary greatly and range from 8 to 62 percent.* This variation is likely due to the myriad of underlying causes of ARDS, the differing degrees of ARDS severity, and the presence or absence of concomitant organ failures. Some of the factors that have been identified as predictors of mortality in pediatric ARDS include P/F ratio, oxygenation index ($[Fio_2 \times$ mean airway pressure$]/Pao_2$), pH, Pediatric Risk of Mortality (PRISM) score (a severity index score commonly used in PICUs), and presence of multiorgan failure.[84] Despite the large reported variation in mortality, it is generally accepted that the overall mortality rate of pediatric ARDS is lower than that of the adult population.[117]

Recent studies suggest that mortality from ARDS may be declining; however, the reason for this overall improvement is not completely clear. The trend toward decreasing ARDS mortality over time began over 20 years ago, before the publication and widespread adoption of low tidal volume ventilation strategy. Low tidal volume ventilation is the only mechanical ventilation strategy that has ever been clearly shown to decrease mortality in ARDS in adult patients in the setting of a randomized clinical study.[104] The extent that protective mechanical ventilation strategy has on mortality in actual clinical care remains to be determined, especially in the pediatric population.[2,66] Changes in organization of ICU care, improvement in supportive care, and improved monitoring capabilities may have accounted for the decreasing trend between the early 1990s and late 1990s (66% vs. 34% mortality, respectively).[2] More recent adult studies in the era of "low-volume ventilation" still report mortality rates of approximately 40 percent in adults with ARDS.[79,110] Similar trends are noted in pediatric patients, with mortality rates falling from 80 percent in the 1980s to approximately 20 percent in the early 2000s and potentially under 15 percent now.[117]

PATHOLOGY AND ROLE OF IMMUNOMODULATORS

Pathology and Pathophysiology

The clinical stages of ARDS coincide with three pathologic stages: the exudative stage, the proliferative stage, and the fibrotic stage. The exudative stage is characterized by accumulation of protein-rich edema fluid into the alveoli. This fluid flux is secondary to diffuse injury to the alveolar-capillary membrane by either direct or indirect injury (see Table 65-1). Neutrophils play a predominant role in this stage of ARDS. In addition to influx of inflammatory cells and mediators, formation of microthrombi within the vasculature contributes further to the ALI and alters the pulmonary vascular tone. Pulmonary compliance is worsened by the presence of edema and can result in widespread atelectasis. Pulmonary compliance is further affected by the inactivation of surfactant that results from the presence of plasma proteins, such as fibrin, and inflammatory mediators, such as proteinases, in the alveolar space.[61,95] The development of microthrombi within the pulmonary vasculature together with the release of numerous vasoactive mediators from inflammatory cells and the activated endothelium contribute to the development of elevated pulmonary vascular resistance and further contribute to the ventilation/perfusion abnormalities characteristic of ARDS. The degree of epithelial injury and the subsequent ability to clear edema fluid, along with the reversibility of pulmonary hypertension, are important predictors of outcome in ARDS.[62,112]

The proliferative stage occurs 1 to 3 weeks after the initiation of injury and is characterized by attempted repair of the disrupted alveolar-capillary membrane. The mechanism of this repair requires not only the close coordination of numerous growth factors but also an intact basement membrane to provide a platform for cell adhesion and migration.[80]

The ability of the lung to recover depends on the presence of functional epithelium to clear the alveolar fluid and the body's ability to attenuate the inflammatory process. The ability of the alveolar epithelium to remove edema fluid depends on the degree of inflammation and injury in the exudative stage. After the initiation of the injury, anti-inflammatory processes take place to limit the degree of injury. Anti-inflammatory cytokines such as

interleukin (IL)-10 and lipid mediators have been shown to be important in the mitigation of this injury.[63] If lung injury and inflammation persist, the patient may develop severe physiologic abnormalities and may progress to the fibrotic stage of ARDS.

The fibrotic stage may be seen as early as 5 to 7 days after the onset of disease, although the presence of this injury becomes more clear after several weeks. Histologically, the alveolar space becomes filled with mesenchymal cells and lung tissue is replaced by collagenous tissue.[54] In addition, vascular changes in the fibrotic stage can lead to increased thickness of the pulmonary vasculature and even obliteration of small capillaries. Overall, these changes markedly decrease the available surface area for gas exchange and result in decreased effort tolerance in survivors of ARDS. In some patients, intractable respiratory failure or chronic lung disease result, necessitating prolonged ventilator support.

Immunomodulators

Numerous mediators of inflammation are implicated in the pathogenesis of ARDS.[88] Some of the more important mediators include tumor necrosis factor (TNF), ILs, and matrix metalloproteinases (MMPs).[36] The identification of these mediators potentially allows for development of biomarkers to predict the severity of ARDS. In a study involving 33 children with ARDS and 21 patients without ARDS who required mechanical ventilation, active MMP-9 in tracheal aspirates was significantly elevated in the ARDS patients. Furthermore, elevation of MMP-8 and MMP-9 at 48 hours predicts a longer duration of mechanical ventilation in children with ARDS, highlighting the potential use of MMPs as a biomarker in pediatric ARDS. The effects of mediators and inflammatory cells involved in ARDS, as well as regulatory molecules, are tightly woven and ultimately result in a balance between proinflammatory and anti-inflammatory and pro-edematous and anti-edematous factors.[37] Although inflammatory mediators could themselves disrupt the capillary-alveolar membrane, they also may exert effects to keep the inflammatory response in check. This may account for the lack of success of pharmacologic inhibitors to decrease the mortality associated with ARDS. Research efforts continue to investigate potential ways to more effectively modulate the inflammatory response during ARDS.[64,88]

Increasing evidence indicates that the genetic makeup of an individual influences the outcome of sepsis and ARDS.[109,115] One of the most commonly studied genetic polymorphisms in sepsis is that pertaining to TNF, which plays a central role in the "cytokine storm" in septic shock. Both pediatric and adult studies have shown that certain single nucleotide polymorphisms (SNPs) regulate the susceptibility of septic patients in developing ARDS.[12,44] A study of 490 children with sepsis found that changes in different SNPs in the TNF genotype affects the risk for developing ARDS (i.e., TNF-308 GA genotype was protective, and TNF-863 CA genotype increases the risk).[12] Genetic polymorphisms may potentially provide useful biomarkers for screening septic children who are at risk for developing ARDS and to identify a subgroup of patients who will benefit most from specific therapeutic strategies.

TREATMENT

The goal in the treatment of patients with ARDS is to treat the underlying disease (when possible), achieve adequate tissue oxygenation, and minimize ventilator-induced lung injury (VILI). In patients in whom ARDS is secondary to sepsis, prompt administration of appropriate antibiotics is essential.[29,58] The general antimicrobial approach depends on the local virulence and pattern of drug resistance in the community and within a given hospital. In the United States, where cases of infection with cephalosporin-resistant *S. pneumoniae* and MRSA are increasing, broad-spectrum gram-positive coverage (e.g., vancomycin) often is necessary.[29,53] The mainstay of support in the ARDS patient is the provision of supplemental oxygen and mechanical ventilation. In addition, nonpulmonary organ function must be meticulously maintained to optimize the clinical care of children with ARDS.

Pulmonary Management

Modes of Mechanical Ventilation

Multiple modes of mechanical ventilation are currently used in clinical practice to provide respiratory support for patients with ARDS. Conventional mechanical ventilation, which delivers tidal volume breaths, can be achieved effectively by either pressure-control or volume-control modes. In the former, the clinician controls the amount of inspiratory pressure in each breath delivered to the patient and, depending on the pulmonary compliance, the patient receives different tidal volumes. In volume-control modes, the clinician determines the amount of volume delivered to the patient and, with changing pulmonary compliance, the inspiratory pressure changes. Regardless of the conventional mechanical ventilation mode(s) used, it is paramount that VILI be minimized by paying meticulous attention to prevention of barotrauma and volutrauma. Prospective, randomized multicenter studies comparing one ventilatory mode to another in the setting of ARDS are limited and have not demonstrated a single ventilatory mode as superior to any other.[34,83]

In contrast to conventional mechanical ventilation, high-frequency oscillatory ventilation is an alternative mode that delivers extremely small-volume "breaths" (i.e., less than dead space volume) at high rates (5 to 15 Hz [equivalent to 300 to 900 breaths/min]). Although use of high-frequency oscillatory ventilation has become commonplace, the only definitive study of this method in pediatric ARDS is a crossover trial conducted nearly 20 years ago that showed improved oxygenation and a reduction in the need for supplemental oxygen at 30 days.[9] Despite the lack of robust evidence in support of high-frequency oscillatory ventilation, it has become a

standard technique in the management of ARDS in PICUs worldwide.[86]

Low Tidal Volume Ventilation

A landmark study of adults with ARDS published in the *New England Journal of Medicine* in 2000 showed that low tidal volume mechanical ventilation (6 mL/kg) decreased mortality by 22 percent and increased the number of ventilator-free days in contrast to a more traditional tidal volume (12 mL/kg).[104] The mortality rate was 31.0 percent in the low tidal volume group and 39.8 percent ($p = .007$) in the higher tidal volume group. Additionally, the plateau pressure (Pplat), a major factor in creating barotrauma in the lungs, was significantly decreased in the low tidal volume group (≤26 cm H_2O) in contrast to the control group (37 ± 9 cm H_2O). This study is the only investigation in either adult or pediatric ARDS that has demonstrated a mortality benefit associated with a specific ventilatory approach. Although still unproved, these results are likely applicable to infants and children with ARDS and this low tidal volume approach has become standard practice in the PICU setting.

Further data from other large mechanical ventilation studies in adults demonstrated that outcomes are improved when Pplat is limited to less than 32 to 35 cm H_2O.[6,18,100] No data exist in pediatric patients to guide practitioners in the establishment of peak inspiratory pressure or tidal volume, and ongoing investigation is needed. It is possible that the "critical" limit on plateau pressure for infants and children may be less than 32 to 35 cm H_2O, or there may be variation with patient age, but without further studies, clinicians must rely on available data on adults and individual clinical expertise. Without a similar large-scale, prospective, randomized trial in pediatrics, a ventilatory strategy should be undertaken that limits both tidal volume and inspiratory pressure.

Positive End-Expiratory Pressure

PEEP is the constant pressure applied to the airways and alveoli during exhalation and is an important component of the ventilator strategies employed in the management of ARDS. PEEP helps maintain alveolar patency and restore functional residual capacity. PEEP is typically titrated to a level that allows adequate oxygenation at an acceptable Fio_2 as described later in more detail.

The ARDS Network investigated the optimal PEEP-Fio_2 approach for adult patients with ARDS and showed that both "lower" and "higher" PEEP strategies produced similar survival rates.[20] The results of this study suggest that as long as adequate PEEP is applied, higher levels are not necessary but are acceptable. Thus, the balance between PEEP and Fio_2 (as long as alveolar collapse is minimized) can be left to the discretion of the clinician. PEEP- Fio_2 tables for adult patients are readily available[10]; however, no such generally accepted standards are available for infants and children. In summary, once appropriate PEEP is applied to maintain the lungs at an ideal volume, a further increase in PEEP in an attempt to reduce the Fio_2 does not lead to an improved outcome.[10]

In a follow-up meta-analysis of almost 2300 patients, Briel and colleagues[16] demonstrated that patients with pure ALI (i.e., recruitable lung) benefited from a higher PEEP strategy, whereas those without recruitable lung did not. Based on these data, a strategy that individualizes PEEP based on the specific clinical circumstances seems warranted.

It must be noted that an important consideration as PEEP is titrated is the impact of increasing mean intrathoracic pressure on systemic venous return and cardiac output. Increasing PEEP comes at a cost of increased mean intrathoracic pressure and potentially a decrease in systemic venous return and cardiac output.[67] As a result of these changes, patients with ARDS may need further intravascular volume loading and possibly inotropic support.[82] A comprehensive discussion of the cardiorespiratory effects of increasing PEEP is beyond the scope of this chapter.

Gas Exchange Goals

Every child with ARDS is hypoxemic by definition. Prolonged administration of high concentrations of oxygen can damage lungs, owing to the formation of oxygen free radicals. Human and animal studies suggest that a prolonged Fio_2 greater than 0.60 should be avoided to prevent oxygen-induced pulmonary damage.[52] However, the exact Fio_2 cutoff for oxygen toxicity in the ARDS patient, especially in children, remains unknown and may be less than 0.60. Increases in the set PEEP may allow for a reduction of the delivered Fio_2.

In the setting of ARDS, improved oxygenation has not been associated with improved outcomes. This finding was best demonstrated in the ARDS Network low tidal volume study, in which the control (12 mL/kg) group demonstrated improved oxygenation for the first 72 hours of mechanical ventilation but ultimately had a higher mortality in contrast to the lower tidal volume (6 mL/kg) group.[104] In a pediatric study of 470 children, no correlation was found between oxygenation or ventilation measured during the first 14 days of PICU admission in survivors or nonsurvivors of pediatric ALI.[106] Other studies in pediatric ARDS have demonstrated short-term improvements in oxygenation parameters with no difference in mortality.[30,31] The ideal target for oxygenation in ARDS remains controversial, but it is clinically reasonable to accept Sao_2 under 90 percent as long as tissue oxygen delivery is adequate, as described later in the discussion of permissive hypoxemia.

Permissive Hypercapnia

A consequence of low tidal volume ventilation is hypercapnia. Limiting the peak inspiratory pressure by reducing the tidal volume may decrease minute ventilation and result in hypercapnia. Limited evidence suggests that low-volume, pressure-limited ventilation with permissive hypercapnia may improve outcomes in patients with ARDS.[47,48] In a 10-year study, Milberg and colleagues[66]

reported a positive association between permissive hypercapnia and outcomes. Recent data from a laboratory model of ischemia-reperfusion ALI indicate that hypercapnic acidosis is protective and that buffering of the hypercapnic acidosis actually attenuates these protective effects.[56]

In addition, permissive hypercapnia has been increasingly studied in animal models with regard to its role in modulating sepsis-induced ARDS.[24,51] Permissive hypercapnia can potentially inhibit the immune response.[57] This inhibition of the immune system is of particular concern in patients with sepsis. However, recent animal studies reported a beneficial effect of hypercapnic acidosis in reducing ALI in early and prolonged systemic sepsis.[23] Earlier concerns that hypercapnic acidosis is harmful in patients with a pulmonary source of the sepsis (i.e., by increasing bacterial load and worsening lung injury) have been addressed by further studies that showed that administration of antibiotics prevented these deleterious effects.[22,73,74] These findings, along with data demonstrating worsening mortality with each hour in which antibiotics are delayed in septic patients,[55] reinforce the need for early administration of antibiotics in the management of pediatric sepsis and ARDS.[17] Despite these potential benefits and evidence suggesting that respiratory acidosis is not harmful, the exact degree of hypercapnia that can be safely tolerated remains controversial. Most of the undesirable effects of hypercapnia are reversible and minor when pH is greater than approximately 7.20.[37] We eagerly await future clinical studies looking at the role of permissive hypercapnia in sepsis-related lung injury given the increasing preclinical evidence of its potential therapeutic role.

Permissive Hypoxemia

In the situation of severe ARDS with elevated ventilator support, clinicians must carefully titrate a balance between avoiding toxic ventilator settings (e.g., elevated airway pressures and Fio_2) and accepting lower than normal arterial oxygen saturations.[1,84] This concept of accepting lower arterial oxygen saturations is termed *permissive hypoxemia*.[1,84] PEEP and other ventilatory parameters should be set so as to optimize oxygen delivery, with tolerance of lower oxygen saturations to allow for minimization of VILI. Because the minimal acceptable arterial oxygen saturation remains controversial the optimal oxygen saturation target for an individual patient remains unknown; however, the goal should be to provide adequate tissue/organ oxygenation while minimizing toxicity of the ventilator settings.

ADJUNCTIVE THERAPIES

Corticosteroids

Given that inflammation is the cornerstone of the pathophysiology of ARDS, corticosteroids have therapeutic potential as immunomodulatory or anti-inflammatory agents. There are, unfortunately, no studies of corticosteroids for treatment of ARDS in children. In the adult ARDS population, an inherent difficulty in summarizing the use of corticosteroids is the significant variability in the timing and dose of steroids used in the various studies. The timing of steroids in published clinical studies ranges from 72 hours to 4 weeks of onset of ARDS, and the doses of methylprednisolone (or its equivalent) range from 1 mg/kg/day to 120 mg/kg/day.[78] Meta-analyses of corticosteroid used within the first 2 weeks in adults with established ARDS demonstrated that steroids may reduce mortality and reduce total days of mechanical ventilation.[78,103] However, based on current data, corticosteroids do not appear to have a role in prevention of ARDS.[78] The use of steroids was not associated with an increase in secondary infections.[78,103]

Inhaled Nitric Oxide

Pulmonary vascular dysfunction has been associated with ARDS and is an important component of the pathophysiologic process.[21] This impact of ARDS on pulmonary vascular tone has led to the extensive investigation of inhaled nitric oxide, a potent vasodilator that works exclusively in the pulmonary vasculature, as a potential therapeutic option. Studies of inhaled nitric oxide for pediatric ARDS have demonstrated temporary improvement in oxygenation acutely but not improved survival.[3,30,31] This finding is similar in the adult population. The largest pediatric inhaled nitric oxide study to date involved 108 children.[31] Because of the crossover design, the study was not able to describe mortality results, but it did demonstrate that the groups of children who may acutely benefit most are immunocompromised patients and those with greater severity of hypoxemia.

A recent Cochrane Database Systematic Review looking at 14 randomized controlled trials concluded that inhaled nitric oxide cannot be recommended for either children or adults with ARDS because it resulted in transient improvement in oxygenation without mortality benefit.[5] Furthermore, it appeared that inhaled nitric oxide may increase the risk for renal impairment among adults with ARDS.

Surfactant Replacement

In ARDS, injury occurs to type II pneumocytes, resulting in decreased production of surfactant. This injury has prompted studies examining the possibility of the effectiveness of surfactant replacement in the management of ARDS. A recent study of 153 pediatric patients reported that exogenous surfactant acutely improved oxygenation and significantly decreased mortality in infants and children with ALI.[114] However, this study revealed no significant decrease in duration of mechanical ventilation, length of PICU admission, or length of hospital stay. The results of this study are controversial because a significantly higher number of immunocompromised patients (i.e., with a higher expected mortality) were included in the control group.[26] Follow-up studies have been completed, and data are currently being analyzed.

The evidence for benefit associated with surfactant therapy in adults also is limited. A large, randomized trial of nearly 450 patients did not show a mortality difference

with use of surfactant.[98] Other studies in adults also have not demonstrated a benefit. Unlike in the neonatal populations, current data do not demonstrate wide-scale benefits associated with surfactant use in pediatric or adult ALI, but there may be select circumstances in which this therapy is beneficial.

Prone Positioning

Through various mechanisms such as improvement in ventilation/perfusion matching and chest wall mechanics, prone positioning was first shown in a randomized controlled trial to improve oxygenation in patients with ARDS by Gattinoni and his Supine-Prone Study group.[41] Despite promising results of prone positioning from investigations in adults with ARDS, a study of prone positioning for pediatric ALI was closed for futility.[25] It is likely that not all children with ARDS will benefit from prone positioning. Experience from clinical studies in adults with ARDS showed that there is likely to be a subgroup of patients who benefit most from this maneuver.[101,102] Future pediatric studies should aim to identify this particular subset of patients.

Nonpulmonary Supportive Management

Fluid Balance

Initial aggressive fluid resuscitation is important in maintaining hemodynamics and improving clinical outcomes in patients with shock.[93] However, overhydration, once hemodynamics are restored, may lead to pulmonary edema. Fluids should be carefully titrated and fluid status monitored while normalizing the patient's intravascular volume status and maintaining adequate cardiac output.[8] The ARDS Network conducted a study to investigate conservative and liberal fluid management strategies in adult patients with ARDS.[113] In this study, a difference of 6000 mL was seen in the 7-day cumulative fluid balance between the two groups; with patients in the conservative fluid management group having improved lung function and shorter duration of mechanical ventilation and ICU length of stay. In critically ill children, the role of fluid balance is less conclusive. Although some studies demonstrate that fluid balance has an impact on oxygenation and morbidity,[8,49] other prospective pediatric studies have shown otherwise.[85] The Pediatric Acute Lung Injury and Sepsis Investigators (PALISI) Network investigators showed that cumulative fluid input and output did not affect the speed of weaning from mechanical ventilation or extubation outcomes.[85]

Sedation and Neuromuscular Blockade

Appropriate sedation and analgesia are important in children who are on mechanical ventilation. Prolonged sedation and neuromuscular blockage have been associated with worse clinical outcomes.[10,40] However, a recent study demonstrated that early neuromuscular blockage improved survival in adults with ARDS.[76] In this study of 340 adults with ARDS, the use of cisatracurium for 48 hours (vs. placebo) improved 90-day survival by nearly 1.5 times without an increase in muscle weakness. In contrast, growing evidence in adults indicates substantial benefits associated with sedation weaning and promotion of early mobilization.[42,70] Given the lack of consistent evidence in both adults and children, the use of neuromuscular blockade in children with ARDS remains controversial. Overall, use of these agents should be driven by a balance between maintaining adequate gas exchange and the potential adverse effects of critical illness weakness and myopathy.

Nutrition

As a general approach, adequate nutrition should be provided to optimize caloric intake and avoid a negative nitrogen balance. However, few studies examining the effects of nutrition in children with ARDS have been conducted. Clinical guidelines with regard to nutritional support of critically ill children are, at best, supported by small, randomized trials with reasonable risk for bias in their results.[65] Two studies in adults with a total of 1200 patients showed that a trophic feeding strategy did not increase the duration of mechanical ventilation or reduce mortality in contrast to full enteral feeding. The patients on trophic feeds, however, had fewer gastrointestinal side effects such as vomiting and constipation.[89,92]

Although a growing number of studies are investigating the potential utility of nutritional supplementation in ARDS, the results have not been consistent or encouraging. Using bronchoalveolar and plasma biomarkers as their end points, investigators examining the effect of omega-3 oil on adults with ARDS did not note any difference in IL-8, IL-6, and leukotriene B4 levels between patients with and without supplementation.[99] This was further supported by a recent clinical study that was stopped early for futility.[91] This study of twice-daily supplementation of omega-3 fatty acids within 48 hours of onset of ARDS showed a trend toward longer duration of mechanical ventilation and higher mortality in the treatment group.[91]

Patient Isolation

Even though infectious etiologies are the most common cause of ARDS in children, routine isolation of all ARDS patients is not warranted. In certain infective etiologies such as viruses (e.g., influenza, RSV, adenovirus), resistant bacteria, and mycobacteria (e.g., tuberculosis), appropriate isolation measures should be instituted.[111]

Rescue Therapies

Some patients with severe ARDS become refractory to maximal therapies and are unable to achieve acceptable therapeutic goals while avoiding oxygen toxicity or intolerably high airway pressures. In these circumstances, ECMO is becoming increasingly used as a rescue for these patients.

ECMO involves withdrawing blood from the patient by a mechanical pump and directing it to a membrane oxygenator, where oxygenation and removal of carbon dioxide occur before the blood is returned to the patient.

In refractory ARDS patients, venovenous ECMO is commonly used, which involves blood being withdrawn from the patient via a cannula placed in a central vein and returned to the venous system. Cardiac function must be sufficient to circulate this returned blood systemically to the body. ECMO has been used successfully in a wide range of clinical circumstances and is a viable treatment strategy in adults and children with refractory ARDS.[19,45] Traditionally, ECMO has been implemented in patients with an anticipated mortality that is extremely high, exceeding 80 to 90 percent in many circumstances, but reported survival from the Extracorporeal Life Support Organization (ELSO) registry for adults and children with ARDS is currently 50 and 65 percent, respectively.[19,32] In the past decade, use of ECMO has continued to increase, as evidenced by reports from the 2009 to 2010 H1N1 influenza A pandemic.[27,71,72,108] A more detailed discussion of ECMO support for pediatric and adult ARDS patients is beyond the scope of this chapter.

SUMMARY

ARDS represents a spectrum of clinical disease of varying pulmonary and nonpulmonary etiologies. Although much progress has been made with regard to understanding the pathophysiology of ARDS, the only ventilatory strategy that has been proved to improve clinical outcome is low tidal volume ventilation. It is anticipated that future clinical studies are likely to combine therapeutic strategies instead of simply focusing on a single intervention. Although meticulous balance is important in each organ system, limited data exist regarding the optimal supportive management strategies for children with ARDS. Current approaches largely represent clinical experience and extrapolation of the available data from the adult population. Without doubt, basic science and genomics studies will continue to be translated into clinical application at the bedside to better individualize treatment strategies for pediatric ALI.

SECTION **XIII**

INFECTIONS OF THE FETUS AND NEWBORN

CHAPTER 66

Approach to Infections in the Fetus and Newborn

Gail J. Harrison

This chapter provides an overview and approach to the diagnosis and management of the more common infections that occur in the fetus and newborn infant. Details about how each organism affects the fetus and newborn, as well as information on diagnosis and management, are covered in the pathogen-specific and disease-specific chapters of this edition.

VIRAL INFECTIONS OF THE FETUS AND NEONATE

Viral infections are an important cause of fetal and neonatal morbidity and mortality. The cumulative frequency of viral infections in the fetus or newborn infant may be as high as 6 to 8 percent of all live births, whereas systemic bacterial disease occurs in only 1 to 2 percent of neonates. Viral infections of the fetus and newborn may be divided into congenital, perinatal or natal, and postnatal time periods of acquisition.

Pathogenesis

Congenital Viral Infections

Congenital viral infections are transmitted to the developing fetus during a maternal infection. Most congenital viral infections are from maternal primary infections, but some viruses (cytomegalovirus) may be transmitted to the fetus during a recurrent (reactivation or reinfection) maternal infection.[7] Congenital viral infections can result in resorption of the embryo; spontaneous abortion; stillbirth; congenital malformation; prematurity; intrauterine growth restriction (IUGR); or acute disease apparent in utero, at birth, or shortly thereafter. Some congenital infections, like most congenital cytomegalovirus (CMV) infections, are seemingly asymptomatic in the fetal or neonatal period, yet may be associated with persistent postnatal infection, sequelae later in life, or a normal infant with no apparent sequelae.

Most fetal infections are preceded by a systemic viral infection in the mother, with hematogenous spread of the virus to the placenta and subsequently to the fetus (Fig. 66-1). Ascending infection through amniotic membranes also may occur while the fetus is still in utero. With most viruses known to cause fetal infection—CMV, rubella virus, herpes simplex virus (HSV), varicella-zoster virus (VZV), and vaccinia virus—placental involvement by the virus also has been documented (Table 66-1). Viruses may reach the fetal circulation by (1) replication through the layers of the placenta; (2) production of virus-induced vascular lesions in the placenta, resulting in abnormal communications between the maternal and fetal circulation; or (3) diapedesis of virus-infected maternal leukocytes through the layers of the placenta to the fetal circulation.

Damage to the fetus also may occur in the absence of actual fetal viral infection as a result of severe systemic illness in the mother, such as measles or influenza, or alteration of placental function. Premature birth occurs in congenital viral infection, as well as small for gestational age as a result of IUGR.

Viruses and Congenital Malformation

Developmental malformations may result from infection of the fetus with certain viruses. Rubella virus is the classic known teratogen, causing disturbances in organogenesis, cardiac disease, and cataracts.[8] VZV has been shown to cause limb hypoplasia and developmental malformations of the eye. Other viruses that result in congenital abnormalities, such as CMV and HSV, usually cause inflammatory, destructive lesions of already developed organs. Type B coxsackieviruses have been associated with a variety of congenital malformations of the heart, and mumps has been linked to endocardial fibroelastosis.

Natal or Perinatal Viral Infections

Natal or perinatal infections are the result of exposure of the newborn to virus replicating in the maternal cervicovaginal tract (i.e., CMV, HSV, or hepatitis B virus) or perirectal area (e.g., enteroviruses). Natal or perinatal infections with some viruses can cause acute systemic illness leading to death, persistent infection with late sequelae, self-limited disease with no discernible damage, or asymptomatic infection (see Fig. 66-1 and Table 66-1). Because the incubation periods of HSV and enteroviruses are short, acute postnatal disease may appear in the neonate within 5 to 7 days of age. In contrast, the incubation periods of CMV and hepatitis B virus (HBV) are

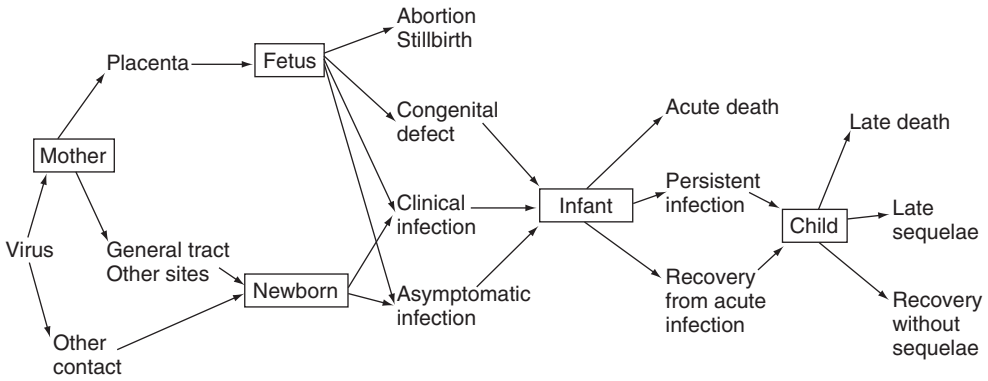

FIGURE 66-1 ■ Pathogenesis of viral infections in the fetus and newborn.

TABLE 66-1 **Period of Transmission of Selected Viruses to the Fetus or Newborn Infant**

Viruses	Congenital	Natal	Postnatal
Adenovirus	+	+	+
Cytomegalovirus	++	++	++
Echoviruses	+	+	+
Epstein-Barr	+	–	+
Hepatitis A	–	++	+
Hepatitis B	+	++	+
Hepatitis C	+	++	–
Herpes simplex	+	++	+
Herpesvirus-6	+	–	+
Human immunodeficiency virus	+	++	+
Human parvovirus B19	+	–	–
Influenza	(+)	–	+
Lymphocytic choriomeningitis virus	++	–	–
Measles	+	–	+
Mumps	+	–	–
Parechovirus	–	+	+
Polioviruses	+	+	+
Rubella	++	–	–
Smallpox	+	+	+
St. Louis encephalitis virus	(+)	–	(+)
Type B coxsackieviruses	+	+	+
Vaccinia	+	+	+
Varicella-zoster	++	+	+
West Nile virus	+	–	+
Western equine encephalitis	+	–	+

++, Major demonstrated route; +, minor demonstrated route; (+), suggested route, few supporting data; –, route not demonstrated.

longer, and clinically apparent disease from perinatal exposure, if it occurs, may not be observed for several weeks or even months after birth. Persistent postnatal infection can occur after perinatal infection with CMV, HSV, and HBV.

Postnatal Viral Infections

Postnatal infections in the neonate may be transmitted to the neonate from the mother, family members, caretakers in extended family, health care workers, outbreaks in neonatal care units, or community exposures (see Fig. 66-1). Neonatal infections and hospital-associated outbreaks of enterovirus and parechovirus, respiratory syncytial virus (RSV), rotavirus, adenovirus, rhinovirus, parainfluenza virus, human metapneumovirus, and influenza virus infection have occurred. In addition, health care–associated HSV infections have occurred in neonates (see Table 66-1). Although the maternal respiratory and gastrointestinal tracts are the most common sites from which virus can be transmitted to the neonate postnatally, other viruses, including human immunodeficiency virus (HIV), human T-cell leukemia virus types 1 and 2 (HTLV I and II), CMV, West Nile virus, rubella virus, hepatitis C virus (HCV), and HBV, have been recovered from breast milk. HSV and VZV lesions on the breast of a mother also may be a source of transmission of virus for the breast-feeding neonate, even though these viruses probably are not present in the breast milk. Finally, HIV, CMV, and HBV have been transmitted to newborn infants by blood transfusion. Although most postnatal infections are acute, self-limited processes, severe disease and fatalities have been reported, especially in preterm infants infected with CMV, enteroviruses, HSV, adenoviruses, or RSV, and persistent postnatal infection may occur with CMV and HBV.[4,5]

Approach to Diagnosis

Clinical Features in Fetus and Newborn

Fetal viral infection may be suspected if the mother is exposed to or experiences an infection with a virus known to transmit to the fetus. Abnormalities detected on routine fetal ultrasound also may suggest fetal infection. Fetal abnormalities detected during prenatal evaluation that may be caused by in utero virus infection include IUGR, microcephaly, cerebral ventriculomegaly or hydrocephalus, cataracts, hepatosplenomegaly, hepatic or intracranial calcifications, polymicrogyria, hydrocephalus, microcephaly, in utero central nervous system (CNS) vasculitis, echogenic bowel, fetal ascites, cardiomegaly,

congestive heart failure, fetal hydrops, enlarged or swollen placenta, or polyhydramnios or oligohydramnios. Intrauterine cardiac abnormalities, myocarditis, and heart failure may be associated with HIV, parvovirus B19, mumps virus, or adenovirus, and cardiac structural defects may be associated with rubella virus. Limb deformities or dysplasias, especially if they are associated with eye or CNS abnormalities, may be caused by intrauterine VZV or HSV infection. Consultation with a maternal-fetal medicine specialist is recommended if fetal viral infection is suspected because prenatal intervention strategies are now available for many of these infections (e.g., CMV and parvovirus B19), which may lessen the morbidity and mortality rates associated with viral infections in the fetus.

Icterus, petechiae, microcephaly, or hepatosplenomegaly at the time of birth or shortly thereafter in a small-for-gestational-age infant suggests a chronic in utero viral infection. On the other hand, acute viral infection in a neonate with suspected sepsis may be present when cultures of blood, spinal fluid, and urine fail to yield a bacterial or fungal agent. Postnatal infections with primarily respiratory virus pathogens may present with apnea, poor feeding, cough, and congestion. In some newborns, involvement of the CNS is the prominent presentation.

Evaluation of the Mother

A history of recent illness or exposures to the mother should be obtained to uncover circumstantial evidence for a viral infection. For example, the occurrence of maternal viral illness with an associated maculopapular rash suggests rubella or enterovirus infection in the neonate, exposure to mosquitoes suggests St. Louis encephalitis virus or West Nile virus, ulcerative genital lesions suggest HSV, and heterophile-negative infectious mononucleosis is suggestive of CMV. Maternal rash with arthralgias may be caused by parvovirus B19, especially if there is recent exposure to fifth disease in the community. One should note, however, that most maternal viral infections that lead to fetal or neonatal infection (almost all cases of CMV and HBV infection and half to two thirds of rubella virus and HSV infections) are asymptomatic in the mother. Therefore, the absence of a history of viral infection in the mother certainly does not rule out the possibility of a viral infection in the neonate.

Clinical Features in the Neonate

Certain clinical manifestations of viral disease in the neonate may provide helpful clues to the specific etiologic agent (Table 66-2). However, most viral infections are asymptomatic in neonates; more than 80 percent of CMV, 60 percent of rubella virus, and most HBV infections. In contrast, fewer than 1 percent of HSV infections in the neonate are subclinical. The clinical and laboratory manifestations of symptomatic disease in the neonate caused by numerous agents often have similar patterns.

Certain specific findings may be helpful in the differential diagnosis. The presence of cataracts, congenital heart disease, bone lesions, or microphthalmos is highly suggestive of rubella, whereas chorioretinitis, cerebral calcifications, and hydrocephaly are more common with congenital infection with CMV, lymphocytic choriomeningitis virus (LCMV), or HSV. The neonate may also experience acute systemic viral infections acquired perinatally or postnatally, most often caused by enteroviruses, HSV, or adenoviruses.[4,5] The features in neonates with these kinds of viral infection resemble those associated

TABLE 66-2 **Common Manifestations of Viral Infections in the Newborn Infant**

Asymptomatic Infection	
Chronic Infection (Early Gestation to Midgestation Congenital)	
GENERAL CHARACTERISTICS	
Manifestations present at birth or shortly thereafter	
Presence of congenital defects	
SPECIFIC FEATURES	
General	Small for gestational age
Central nervous system	Microcephaly, seizures, cerebral calcification, hypertonia or hypotonia, cerebrospinal fluid pleocytosis, encephalitis, hydrocephalus, hearing loss
Skin	Icterus, petechiae, purpura, vesicles, hypopigmentation
Eye	Chorioretinitis, cataracts, glaucoma, microphthalmos, optic atrophy
Heart	Patent ductus arteriosus, pulmonary artery stenosis
Abdomen	Hepatosplenomegaly, hepatitis
Lung	Pneumonitis
Musculoskeletal	Bone lesions, limb hypoplasia
Acute Infection (Late Gestation Congenital, Natal, or Postnatal)	
GENERAL CHARACTERISTICS	
Manifestations usually appear several days to weeks after birth	
Absence of congenital defects	
SPECIFIC FEATURES	
General	Hyperthermia or hypothermia, irritability, lethargy, jitters, poor feeding, vomiting
Central nervous system	Seizures, hypertonia or hypotonia, full fontanelle, meningitis, encephalitis, hearing loss
Skin	Icterus, petechiae, purpura, vesicles, maculopapular rash
Eye	Conjunctivitis, keratitis
Heart	Myocarditis
Abdomen	Hepatosplenomegaly, hepatitis
Lung	Pneumonitis, respiratory distress, cyanosis

with bacterial sepsis: lethargy or irritability, fever or hypothermia, respiratory distress, cyanosis, anorexia or vomiting, hepatomegaly, seizures, or abnormal movements. Skin lesions or rashes may not be present. Laboratory abnormalities also may show neutropenia, lymphocytosis, lymphopenia, thrombocytopenia, elevated liver transaminases, hyperbilirubinemia, and cerebrospinal fluid (CSF) pleocytosis. Neonatal viral infection should be included in the differential diagnosis and management plans of neonates with sepsis syndrome, especially if routine bacterial cultures are negative at 24 hours. Aseptic meningitis in the neonate may be caused by perinatal or postnatal infection with HSV 1 or 2, enteroviruses, or parechoviruses. In neonates with persistent severe viral infections, minimally responsive to antiviral therapy, primary immune deficiency disorder of T or B or natural killer (NK) cell function should be considered.

Differential Diagnosis

The differential diagnosis in a fetus or newborn infant with a suspected viral infection includes, but is not limited to, bacterial or fungal sepsis, toxoplasmosis, syphilis, erythroblastosis fetalis, metabolic inborn errors of metabolism, genetic chromosomal abnormalities, and other forms of congenital malformations.

Laboratory Diagnosis

The most direct, definitive, and preferred method of establishing the diagnosis of a congenital, perinatal, or postnatal viral infection is isolation or molecular detection by polymerase chain reaction (PCR) of the viral agent from an appropriate site in the fetus or neonate. Prenatal diagnosis of fetal viral infection may be established by testing amniotic fluid for viral culture and PCR and, rarely, by fetal blood sample or viral-specific immunoglobulin (Ig)M and PCR. If a congenital infection is suspected in the delivery room, the placenta should be sent for histopathologic studies.

In neonates, urine, saliva, and blood for CMV; throat, cataracts, and occasionally CSF or urine for rubella; skin vesicles, blood, CSF, conjunctivae, throat, stool, and urine for HSV; throat, stool, urine, CSF, or blood for enteroviruses; and skin vesicles and blood for VZV should be sent for virus isolation and virus detection by PCR. In addition, isolation or molecular detection by PCR of virus can be attempted from biopsy or autopsy specimens. Electron-microscopic examination of vesicle fluid or tissue can demonstrate typical herpesvirus particles in both HSV and VZV infection but cannot distinguish between the two. Dried blood spots archived after completion of newborn screening for metabolic and immunodeficiency disorder, may be retrieved through state newborn screening agencies and tested for presence of viral DNA.[2,3] Such approaches have reliably allowed the retrospective diagnosis of congenital CMV. Research evaluating urine and saliva as screening specimens for congenital CMV infection have also been conducted.[2,3,7]

Serologic methods should be used only when isolation or histopathologic or molecular detection by PCR of the virus organism is not possible. The TORCH serologic screen for antibodies (*Toxoplasma*, other, rubella, cytomegalovirus, and herpes simplex) was developed for this purpose and may be the diagnostic test available in rural or remote areas of the world. Maternal IgG, which contains antibody against viruses to which the mother has been exposed, passes transplacentally, beginning at midgestation. Peak levels are reached in fetal serum at the time of birth (umbilical cord blood); they decline to undetectable levels by the time that the infant reaches 6 to 12 months of age, depending on the virus. However, the use of more sensitive assays for IgG antibody detection, such as immunoblotting, has demonstrated that maternal IgG antibody may persist for as long as 15 to 18 months.

In contrast, maternal IgM antibody normally is not passed transplacentally.[17] Because the fetus is in a "protected" environment and usually does not receive an antigenic challenge in utero, fetal immunoglobulin levels remain low and do not begin to rise until after birth, when exposure to a variety of antigens occurs. However, the fetus is capable of mounting a humoral immune response when exposed to an antigen (a virus) in utero. Elevated levels of fetal immunoglobulins, therefore, can be detected at birth in umbilical cord blood. Because maternal IgG is present in such high concentration in cord blood serum, assays for IgM are performed. A fetus challenged in utero with a virus can have specific IgM antibodies against the viral agent, as well as elevated levels of the total IgM fraction. Often, a fetus with detectable virus-specific IgM will have severe in utero disease caused by the virus. Typically, three approaches can be used to make a serologic diagnosis of viral infection in a newborn infant: (1) assay of maternal serum and serum specimens from the infant at birth and at 5 to 6 months of age for antiviral antibody (predominantly IgG activity), (2) assay of neonatal serum for IgM antibody against a specific viral agent, and (3) assay of neonatal serum for quantitative IgM levels, a nonspecific indication of antigenic challenge in utero.

The presence of IgM antibodies in maternal, fetal, or neonatal serum against a specific virus usually is considered to be diagnostic of acute or recent infection with that agent. However, both false-positive and false-negative results can occur. False-positive findings can result from cross reaction between viruses, especially the herpesviruses,[4,5,8] and the presence of rheumatoid factor (i.e., IgM antibody that binds to the Fc portion of IgG) in serum. False-negative results can occur because of a poor or delayed humoral immune response in the fetus or neonate. For example, CMV IgM antibody was present in the serum of only 70 percent of congenitally infected infants, as demonstrated by isolation of virus from urine in the first few days of life.

The presence of IgM antibodies specific for HBsAg, CMV, parvo B-19, rubella or other viruses in maternal serum or isolation of HSV from the genital tract or an enterovirus from the stool at the time of delivery provides circumstantial evidence for the cause of the neonate's condition. Although the presence of specific IgM antibody against CMV, rubella virus, parvovirus B19, or HSV in a single maternal serum specimen is highly suggestive of recent infection, IgM tests may produce false-positive

results and need to be interpreted accordingly. Use of CMV IgG avidity testing may be helpful in some circumstances to determine the time of the maternal infection.[17]

Treatment

Intravenous acyclovir followed by long-term oral suppression with oral acyclovir is the mainstay for antiviral treatment of neonatal herpes simplex virus infection.[4,5,12] Congenital CMV disease, especially if it is severe or involves the CNS or sensory organs such as the eye and ear, may be treated with intravenous ganciclovir or oral valganciclovir.[7,11] Neonates with influenza virus may receive antiviral medications, such as oseltamivir, and ribavirin for severe RSV disease.

BACTERIAL DISEASES OF THE FETUS AND NEWBORN

Worldwide, millions of neonates die every year of bacterial infection.[13] In the United States, the infant mortality rate is approximately 6.85 infant deaths/1000 live births. Neonatal bacterial sepsis corresponds to the eighth leading cause of fatality. The incidence of neonatal sepsis ranges from 1 to 8/1000 live births, with the higher figures corresponding to developing countries. Low birth weight, male sex, and congenital malformation are important risk factors. Extreme prematurity is the greatest risk factor for early-onset sepsis and is associated with an increased risk for having adverse outcomes, including respiratory distress syndrome, bronchopulmonary dysplasia, severe intraventricular hemorrhage, and periventricular leukomalacia. The highest age-specific incidence of bacterial meningitis appears to occur during the first month of life.

Epidemiology and Pathogenesis

Throughout pregnancy and until the membranes rupture, the infant's environment usually is sterile. Not until delivery and the immediate neonatal period is the infant exposed to many microorganisms. The human birth canal is host to large numbers of aerobic and anaerobic bacteria, *Mycoplasma*, *Ureaplasma*, *Chlamydia*, fungi, yeast, and viruses. *Staphylococcus epidermidis*, lactobacilli, diphtheroids, and α-hemolytic streptococci are found in 50 to 100 percent of vaginal cultures of pregnant women and constitute the predominant aerobic flora. Significant but less common isolates include *Gardnerella vaginalis*, *Proteus*, and *Klebsiella* spp. and group B and D streptococci; *Staphylococcus aureus* and miscellaneous organisms, such as *Citrobacter*, *Acinetobacter*, and the *Campylobacter* group, are identified even less commonly. Approximately 85 percent of women with genital colonization by anaerobes harbor *Bacteroides* spp., including *Bacteroides fragilis* in a third of cases. Anaerobic streptococci, *Peptostreptococcus* and *Peptococcus*, are found in approximately 40 percent of women, and *Clostridium* is present in 20 percent. Uncommon anaerobic isolates include *Veillonella*, *Bifidobacterium*, and *Eubacterium*. Vaginal cultures of pregnant women yield mixed aerobic and anaerobic species, but the number of anaerobes decreases from early pregnancy to delivery.

Certain microorganisms are associated with the occurrence of stillbirths. Among these bacterial agents are *Escherichia coli*, group B streptococci (GBS), *Ureaplasma urealyticum*, *Listeria monocytogenes*, and *Treponema pallidum*. In countries with a high prevalence of syphilis, as many as half of all stillbirths are caused by this bacterium. In the United States, stillbirths occur in nearly 7/1000 births, and 10 to 25 percent of them appear to be caused by a maternal or fetal infection. In developing countries, the relative contribution of infection may be even greater.

During the process of delivery, encounters with some of these bacteria initiate colonization of the infant's respiratory and gastrointestinal tracts. In most infants, the microbial flora is established without incident; however, disease caused by one of these organisms develops occasionally in an infant. The conversion from colonization to disease produces fetal or neonatal sepsis or other bacterial illnesses.

A greater susceptibility of male infants is more evident in cases of sepsis caused by gram-negative enteric bacilli. The reasons behind this male preponderance are unknown but may be related to sex-linked factors in host susceptibility.

The bacterial cause of neonatal sepsis and meningitis varies from one geographic area to another, and has varied over time.[13] Although bacterial causes of neonatal sepsis in Western European countries are similar to those in the United States, a different pattern has been identified in Latin America, Asia, and Africa. In the latter sites, gram-negative rods are the most frequent pathogens, followed by *S. aureus*.

Streptococcus agalactiae, or GBS, is a major pathogen for the neonate, causing both early-onset sepsis and late-onset disease, usually meningitis, but also other manifestations (Table 66-3). The acute septicemic form of GBS disease can be caused by any of the group B types (B_I to B_{VIII}), and the specific B type causing disease in the infant

TABLE 66-3 **Common Bacterial Pathogens Causing Neonatal Sepsis**

Gram-Negative Organisms
Escherichia coli
Haemophilus influenza
Citrobacter

Listeria monocytogenes
Coagulase-negative staphylococci
Staphylococcus aureus

usually is found in the maternal vaginal tract. GBS meningitis is caused almost exclusively by the B_{III} organism. These organisms may be acquired from nonmaternal sites. Clusters of three or four cases of GBS meningitis have occurred in nurseries during short intervals, suggesting health care–associated outbreaks may occur. The administration of intrapartum antibiotics, such as ampicillin, has reduced the incidence of early-onset GBS disease in neonates. *E. coli* is the other important agent implicated in neonatal bacterial disease, including sepsis and meningitis and urinary tract infection, with an annual incidence of approximately 6.8/1000 live births, and it is the most common gram-negative bacterium causing meningitis during this period.[1] Sepsis caused by *E. coli* is associated with greater morbidity and mortality rates in some studies than is early-onset GBS infection. Ampicillin-resistant *E. coli* strains also may be emerging with more frequency as intrapartum prophylaxis becomes routine. Neonatal colonization with *E. coli* often results from maternal transmission during delivery. Thus, vaginal colonization, observed in 3 to 20 percent of pregnant women, seems to be an important step in neonatal infection. Vertical (mother-to-infant) and horizontal (nursery staff–to-infant, infant-to-infant) modes of transmission have been documented for *E. coli* K1 infections.

Klebsiella pneumoniae is one of the most important neonatal pathogens, causing sepsis and meningitis, in developing countries, with an incidence between 4.1 and 6.3/1000 live births and fatality rates of 18 to 68 percent. It is the second most frequent gram-negative organism associated with late-onset sepsis in developed nations. Although *Klebsiella* strains are part of the normal gastrointestinal and vaginal flora, the resistant nature of the hospital isolates indicates their presence in contaminated environmental reservoirs.

L. monocytogenes is a foodborne colonizer of the human gastrointestinal tract, and one of the host factors that increases the risk for *Listeria* infection and disease is pregnancy. Perinatal infection constituted 34 percent (470/1378) of cases of listeriosis. Transmission to the fetus in utero may produce granulomatous fetal disease, and an early-onset sepsis syndrome or a late-onset meningitis may occur in the neonate perinatally.

S. aureus is another important bacterial neonatal pathogen, causing sepsis, meningitis, osteomyelitis, and abscesses in newborns postnatally. Since the 1980s, epidemic and endemic colonization and disease of the newborn infant with community-acquired and hospital-acquired methicillin-sensitive and methicillin-resistant *S. aureus* (MSSA and MRSA) have been reported with increasing frequency in the United States and Europe. Epidemics of disease caused by MRSA have been reported in the United States and several other countries. Risk factors associated with the development of MRSA infection include lengthy hospitalization, previous antibiotic administration, overcrowding and understaffing, and the presence of predisposing factors such as indwelling central venous catheters, cerebrospinal shunts, mechanical ventilation, and prematurity. Potential reservoirs of MRSA in the hospital environment include colonized or infected neonates, hospital personnel, and the hospital inanimate environment. MRSA is spread by contact and by air and may circulate among patients, staff, and visitors for several months during an outbreak in hospitals, long-term care facilities, and the community. Although chronic nasal carriage of MRSA by hospital personnel has been implicated in several hospital outbreaks, it generally is an uncommon event and is not necessary for initiation or propagation of hospital outbreaks. Limited data suggest that the hospital inanimate environment may become contaminated with MRSA, thereby possibly sustaining outbreaks of infection. Colonized patients without clinical disease contribute substantially to the inpatient reservoir of MRSA. In recent years, an increase in the incidence of community-acquired MRSA infections has occurred in healthy patients without obvious risk factors.

S. epidermidis and other coagulase-negative staphylococci also have been found increasingly to be important neonatal pathogens and a common cause of late-onset sepsis and infections associated with indwelling devices. They are the most common species of the normal flora on the skin, nasal mucosa, and umbilicus of the newborn. With sensitive culture techniques, rates of colonization of the nose, umbilicus, gastrointestinal tract, and cutaneous areas of the neonate with coagulase-negative staphylococci can be as high as 83 percent at 4 days of age. The ubiquitous presence of the organisms and their tolerance to drying and temperature changes contribute to the increased presence of coagulase-negative staphylococci in neonates. Most studies have shown that infections with coagulase-negative staphylococci are not associated with significant mortality rates or morbidity in infected infants.

Enterococcus faecalis and *Enterococcus faecium* are members of the group D streptococci (enterococci), are normal inhabitants of the gastrointestinal tract, and can cause invasive disease in the neonate, usually urinary tract infections, sepsis, and meningitis. These bacteria are the third most frequent gram-positive organisms associated with late-onset sepsis. Outbreaks of bacteremia and meningitis caused by *E. faecium*, resistant to ampicillin and vancomycin, have also now been reported in neonates.

Sepsis Neonatorum

Sepsis neonatorum, or sepsis of the newborn, is a bacterial disease of infants 30 days of age or younger, most often in the first week of life.[15] It involves primarily the bloodstream, although spread to the meninges or other organs occurs in a substantial portion of affected infants. No obvious focus of infection of the bloodstream can be found in most cases.

In utero infection is identified by the presence of bacteria in blood obtained at delivery. Signs of fetal distress, such as tachycardia in second stage of labor, may be the first indication of infection, such as congenital sepsis or pneumonia, in the fetus.

The major signs and symptoms of sepsis in the newborn relate to disturbances in thermoregulation, respiration, heart rate, and gastrointestinal function, abnormalities in temperature regulation—hypothermia or hyperthermia—tachypnea, grunting respirations, cyanosis, intercostal and substernal retractions, and apnea. A heart rate persistently in excess of 160 beats per minute, or above

average for age and gestation, can be a sensitive indicator of early-onset neonatal sepsis. Other early signs of neonatal sepsis include poor feeding, regurgitation, vomiting, weak sucking, abdominal distention, diarrhea, jaundice, and, rarely, gallbladder distention.

Neonates may have cutaneous findings with onset of sepsis neonatorum, which may provide clinical clues for the cause of the condition. Such findings include cellulitis or abscesses (*Staphylococcus* or *Streptococcus*); papular (i.e., listeriosis), vascular, or bullous lesions (i.e., *Pseudomonas*); and exfoliative dermatitis (i.e., phage group II staphylococcal disease). Jaundice develops in approximately one third of infants with sepsis and can also occur in infants with urinary tract infection. Occasionally, jaundice is the only sign of infection and occurs in septic infants, regardless of the type of bacterial pathogen.

Bacterial sepsis in the newborn may be caused by almost any gram-positive or gram-negative organism.[1,15] The most commonly identified bacteria include GBS, group A streptococcus (GAS), and group D streptococcus (GDS), including the enterococci and viridans streptococci. In addition, *Streptococcus pneumoniae* may cause severe illness in the neonate. The gram-positive rod *L. monocytogenes* is also a well-recognized cause of neonatal sepsis. The staphylococci, including community-acquired and hospital-acquired MSSA and MRSA *S. aureus* and coagulase-negative staphylococci may cause sepsis in the newborn. Gram-negative enteric organisms, such as *E. coli* and *K. pneumoniae*, are common causes of neonatal sepsis. In addition, other gram-negative organisms, such as *Enterobacter cloacae* and *Acinetobacter* spp., may cause sepsis in the neonate. *Haemophilus influenzae* also has been isolated from neonates with sepsis.

Recovery of an organism in culture from a meaningful site, such as blood, CSF, urine, abscesses, pleural and peritoneal spaces, joints, bones, and middle ear cavities, substantiates the clinical impression of systemic bacterial disease in the neonate. Isolation of an organism from mucocutaneous sites, such as the skin, ear canal, nasopharynx, gastric aspirate, and rectum, usually does not reflect the microbiologic status of normally sterile body fluids or tissues.

Several sites to sample blood for culture give reliable results: peripheral vein, umbilical artery, and capillary blood. The preferred site is the peripheral vein. Venipuncture should be performed after the skin has been prepared properly by cleansing with an iodine-containing solution. A two-phase antisepsis procedure using 70 percent isopropyl alcohol followed by chlorhexidine or povidone-iodine has been shown to be superior to one using chlorhexidine or povidone-iodine alone in reducing skin colonization by *S. epidermidis*. The theoretical minimal amount of blood needed for detecting bacteremia is a function of the number of organisms circulating at any given time. Infants with *E. coli* sepsis have 5 to more than 1000 colony-forming units per milliliter of blood. Culturing as little as 0.2 mL of blood should be sufficient for detecting *E. coli* bacteremia in these patients. On the basis of experimental *E. coli* sepsis in rabbits, a cultured volume of blood of 0.2 mL is as sensitive as is 1 mL in detecting bacteremia at a threshold level of 5 organisms per milliliter of circulating blood. To improve culture sensitivity, a prudent procedure is to obtain at least 0.5 to 1 mL of blood for culture in infants aged birth to 2 months. Optimal results are obtained when the cultured volume of blood is 5 to 10 percent of the total amount of liquid growth medium to be inoculated.

Bacterial growth is seen in most blood cultures within 24 to 48 hours. Generally, experts recommend obtaining one or two blood cultures before initiating antibiotic therapy. Urine and CSF should be obtained for examination and culture before starting antibiotic therapy in most neonates.

Abnormalities in the white blood cell (WBC) count may be observed, with elevation, left shift with neutrophil predominance, leukemoid reaction, or neutropenia, with thrombocytopenia. The presence of severe thrombocytopenia, or less than 50,000 cells/mL, within 72 hours of birth is an uncommon occurrence and may be caused by early bacterial infection (e.g., GBS sepsis) or congenital viral infection (CMV or HSV). Late-onset thrombocytopenia is often caused by bacterial sepsis or necrotizing enterocolitis. In these cases, platelets fall rapidly, with a nadir at 24 to 48 hours, to counts less than 50,000 cells/mL and tend to persist until the infection is controlled. Slow recovery of platelet counts over a period of 1 to 2 weeks is common.

Elevation of C-reactive protein (CRP) and erythrocyte sedimentation rate (ESR) also may occur.[16] The ESR in infected patients generally is elevated above the normal range of 1 to 2 mm/hr at 12 hours of age to 17 to 20 mm/hr at 14 days of age. Elevated rates usually are not observed until 24 to 48 hours after clinical signs of disease first occur. Other acute-phase reactants, such as CRP, haptoglobin, prealbumin, and transferrin, may be useful in establishing the diagnosis of neonatal sepsis and in monitoring the course of the infection. The most extensively studied of these acute-phase reactants is CRP. Concentrations of this protein increase significantly within a few hours of the onset of infection. In general, other perinatal events have little impact on neonatal CRP values. CRP concentrations decrease rapidly in infected neonates who respond to therapy and, conversely, are elevated persistently in neonates whose infections fail to respond to therapy. Reliance on a single CRP determination as an early indicator of neonatal bacterial infection is not recommended. Serial determinations are helpful, especially in combination with other hematologic tests, when making a decision to stop antimicrobial therapy safely.

When the diagnosis of sepsis is suspected and after the appropriate samples have been obtained for culture, antibiotic therapy should be instituted. Infants with suspected sepsis and no unusual risk factors usually should be treated with a combination that includes a penicillin class of antibiotic and an aminoglycoside. The choice of antibiotics must be based on the infectious history of the nursery, the antimicrobial susceptibilities of bacteria recently isolated from sick and healthy neonates, the probable etiologic agent based on clinical and epidemiologic clues, CSF penetration of antibiotics, and the infant's hepatic and renal function. For treating early-onset sepsis neonatorum, ampicillin and gentamicin are usually initiated. Ampicillin is effective in vitro and

clinically against GBS, *Listeria*, *Proteus*, most enterococci, and 15 to 30 percent of current *E. coli* strains. The aminoglycosides have broader antimicrobial activity against many Enterobacteriaceae, including most *E. coli*, *Klebsiella-Enterobacter*, and *Proteus* strains, and against *P. aeruginosa*. Although gentamicin frequently is used, the choice of aminoglycoside (e.g., gentamicin, amikacin, or tobramycin,) should be based on the antimicrobial susceptibility of nosocomial bacteria within individual nurseries. For infections caused by gentamicin-resistant coliforms, amikacin or third-generation cephalosporins such as cefotaxime and ceftazidime, or extended-spectrum penicillins and β-lactamase inhibitor, such as piperacillin-tazobactam or ticarcillin-clavulanate, should be used.

Cephalosporins are not active against *Listeria* or enterococci and should not be used without concomitant administration of ampicillin in most neonates. Moreover, when used with ampicillin, cephalosporins do not offer the advantage of synergism that aminoglycosides do against strains of enterococci. Staphylococci may cause neonatal sepsis, and antimicrobial therapy against them, with nafcillin or vancomycin, should be initiated if significant risk factors, such as indwelling vascular catheters, abscesses, or cellulitis, exist for staphylococcal infection. Therapeutic drug monitoring is recommended when aminoglycosides are used, especially in low-birth-weight neonates, and adjustment of the dosage is essential for infants with impaired renal function. Some experts recommend extended intervals for aminoglycoside administration in the neonatal period, and guidelines for drug monitoring in these circumstances have been developed.

Late-onset sepsis neonatorum may be caused by a variety of bacterial organisms.[1] In a previously healthy infant who already has been discharged from the hospital, ampicillin and an aminoglycoside or cefotaxime is usually recommended unless staphylococcal infection is highly suspected, in which case an antistaphylococcal agent (e.g., nafcillin or vancomycin) should replace ampicillin.

Selection of empirical antibiotic regimens can be more difficult for a septic premature infant who has had a prolonged hospitalization, previous antibiotic therapy, possible prolonged tracheal intubation, and placement of a central or peripheral intravascular catheter. In these patients, major pathogens include coagulase-negative and coagulase-positive staphylococci (including MRSA), aminoglycoside-resistant coliforms, highly resistant opportunistic organisms (e.g., *Pseudomonas*, *Serratia*), fungi, and possibly enterococci. As a result, empirical regimens in this situation should be individualized. Examples include ampicillin, amikacin, and clindamycin or piperacillin-tazobactam alone for suspected necrotizing enterocolitis, vancomycin and an aminoglycoside or cefotaxime for patients with indwelling central vascular lines, and nafcillin and an aminoglycoside for babies with skin infection suspected to be caused by susceptible staphylococci. In institutions with a high prevalence of MRSA infection, vancomycin generally is used as initial therapy for suspected staphylococcal disease. For infants who do not respond to antimicrobial therapy or have superficial cultures positive for *Candida albicans*, empirical use of amphotericin or fluconazole should be considered. Ceftazidime and cefotaxime usually should not be used routinely in neonatal units because of the potential for emergence of resistant *Enterobacter* and *Serratia* spp.

After culture and susceptibility studies are available, changes in therapy may be necessary. Ampicillin is preferred for susceptible enterococcal and *Listeria* infections, whereas ampicillin or penicillin can be used for GBS disease. Infants infected with these organisms usually receive a combination of ampicillin and an aminoglycoside for the first 3 to 5 days, followed by ampicillin for the balance of 7 to 10 days or longer. For *S. epidermidis* and MRSA infections, vancomycin is the drug of choice. In selected neonates, the addition of rifampin to vancomycin therapy may be beneficial in clearing persistent bacteremia or infections of the CNS. Central venous catheters or other foreign bodies frequently must be removed to eliminate the source of these organisms. If a gram-negative enteric isolate is susceptible to ampicillin and aminoglycosides, treatment with either antibiotic alone or with two antibiotics until the bloodstream is sterile, can be adequate. For *Pseudomonas* infections, combined therapy with ticarcillin, piperacillin, or ceftazidime and an aminoglycoside often is used for the duration of therapy; however, some experts recommend monotherapy once bloodstream infection has sterilized. In certain circumstances, antibiotics such as cefepime, imipenem or meropenem, and ciprofloxacin may be used to treat an infection caused by a multidrug-resistant gram-negative isolate. The duration of antimicrobial therapy for uncomplicated neonatal sepsis caused by a susceptible organism usually is at least 7 to 10 days or approximately 5 to 7 days after the clinical signs and symptoms, laboratory abnormalities, and positive cultures from infection have disappeared. Longer periods of treatment may be necessary in some neonates with complicated or persistent infections. Delayed clinical improvement or persistently positive blood cultures during therapy may indicate that antibiotics may need to be adjusted based on susceptibility of the organism isolated, or that occult sites of infection (e.g., endocarditis, abscesses, infected foreign bodies or indwelling catheters) exist.

For infants whose initial bacterial cultures are sterile after 48 to 72 hours of incubation, and the clinical suspicion for bacterial infection is low, antimicrobial therapy can be discontinued. If no pathogen has been isolated but bacterial sepsis cannot be excluded, a negative CRP test at 72 hours can help support the decision to discontinue antibiotics.

In addition to antibiotics, supportive care with careful attention to fluid and electrolyte balance; correcting hypoxia, acidosis, hypoglycemia, and other metabolic abnormalities; and providing nutritional support are necessary. Human immunoglobulin for intravenous use in septic neonates appears to be safe, but not convincingly proved to be beneficial in randomized clinical trials. In neonates with primary immunodeficiency syndromes involving B cell function that cause reduced levels of immunoglobulin, replacement therapy with immunoglobulin may be needed. Other supportive therapeutic options for critically ill neonates include extracorporeal membrane oxygenation and immunomodulating

strategies (e.g., anticytokine agents, steroids, pentoxifylline, and nitric oxide inhibitors).

Prevention of neonatal sepsis is a priority for clinicians and physician research scientists. Intrapartum chemoprophylaxis given to women at 35 to 37 weeks gestation with proved GBS colonization reliably prevents colonization of the newborn in the postpartum period and reduces early-onset sepsis caused by GBS. Therefore, universal prophylaxis of all pregnant women with GBS colonization is now recommended and is the current cornerstone for prevention of early-onset GBS disease.[1,20] Clinical trials evaluating maternal immunization with GBS as a way to prevent neonatal GBS disease are under way. Currently, no licensed vaccine against GBS exists; however, many experts feel this strategy, when available, will be the most effective and sustainable long-term preventive strategy for neonatal GBS disease.

Prevention of early sepsis caused by gram-negative bacilli by administration of intrapartum aminoglycosides is important in developing areas of the world where these organisms are prevalent, but no standardized guidelines exist.

Prevention of late-onset infection, as opposed to early-onset disease, in neonates by the administration of intravenous immunoglobulin to preterm babies has undergone intense clinical scrutiny, but consensus of summaries of clinical trial evidence does not support its routine use at this time.[20]

Bacterial Meningitis

As many as a fourth of neonates with bacterial sepsis have a simultaneous meningeal infection.[9,18] The incidence of neonatal meningitis varies greatly among institutions in North America. Rates are approximately 0.2 to 0.4 case/1000 live births but may be as high as 1/1000 live births in some nurseries. In general, group B β-hemolytic streptococci (GBS) and *E. coli* strains account for two thirds of all cases of neonatal meningitis in North America. Gram-negative enteric bacilli predominate in many developing areas of the world.

The early signs and symptoms of neonatal meningitis frequently are indistinguishable from those of septicemia and other disorders occurring in the neonatal period. The most frequent signs of neonatal meningitis are temperature instability, respiratory distress, irritability, lethargy, and poor feeding or vomiting. GBS occasionally has been reported to manifest as hydrocephalus without other signs of infection. Signs of meningeal involvement, such as a stiff neck, bulging fontanelle, seizures, and opisthotonos, usually are not present in neonates with meningitis. Therefore, newborns being evaluated for sepsis usually should undergo examination of CSF, especially if antimicrobial therapy is to be instituted.

Abnormal CSF parameters, with elevated WBC count with polymorphonuclear leukocyte predominance, hypoglycorrhachia (low glucose), elevated protein concentration, and positive Gram-stained smear with a positive bacterial culture are the classic and definitive methods to diagnose bacterial neonatal meningitis. However, bacterial meningitis may be present even in the absence of these abnormalities.

Interpretation of CSF values in newborn infants may be difficult. During the first several days of life, the mean WBC count is 15 ± 30 cells/mm^3 (95% confidence limit, 12 to 18 cells/mm^3) in the CSF of healthy or high-risk uninfected babies. Approximately 60 percent of these cells are polymorphonuclear leukocytes. During the first week of life, the cell count slowly diminishes in term infants and increases in premature infants. Cell counts in the range of 0 to 10 cells/mm^3 (median, 4 cells/mm^3) are observed in infants at approximately 2 to 4 weeks of age. The WBC count is unclear when bleeding occurs after the lumbar puncture has been performed. The fixed relationship between the number of WBCs in CSF and peripheral blood may be helpful, and a repeat lumbar puncture may be necessary in 12 to 24 hours to resolve the ambiguity of the traumatic lumbar puncture.

The mean cerebrospinal protein concentration in the first month of life is 64 ± 24 mg/dL, although individual values can be as great as 170 mg/dL, especially in low-birth-weight, premature infants. The ratio of cerebrospinal glucose to blood glucose is 60 to 70 percent and can be greater than 100 percent in term and preterm infants. The upper limits of normal for cellular and chemistry values are higher in uninfected infants with very low birth weight.

These data indicate that CSF values must be interpreted in relation to these normal findings for age and gestation if a diagnosis of neonatal meningitis is to be made early. Comparison of the results of initial CSF evaluations obtained from newborns with proved bacterial meningitis with those from normal or high-risk infants revealed considerable overlap in the findings. For example, approximately 30 percent of infants with GBS meningitis had normal spinal fluid leukocyte counts (<32 cells/mm^3), whereas only 4 percent of neonates with meningitis caused by gram-negative organisms had normal counts. The ratio of CSF to blood glucose was normal in 45 percent and 15 percent of patients with streptococcal and coliform meningitis, respectively. However, when the total CSF evaluation (including Gram-stained smears) was considered, fewer than 1 percent of babies with bacteriologically proved meningitis had totally normal CSF on initial lumbar tap. The likelihood of suppurative meningitis is diminished greatly but not impossible if evaluation of CSF discloses no abnormalities. In some patients in whom the diagnosis is obscured, a repeat CSF examination performed 4 to 6 hours after the initial tap (regardless of whether therapy has been instituted in the interim) may help establish the diagnosis. In premature infants with meningitis caused by *S. epidermidis*, the CSF analysis may be only mildly abnormal despite compatible clinical findings. Careful examination of the stained smears of CSF from every infant with suspected meningitis is important. Grossly clear fluid may contain few WBCs and many bacteria. The stained smears from approximately 20 percent of neonates with proved meningitis are interpreted as showing no bacteria. Because of the low concentrations of organisms, most Gram-stained smears of CSF from infants with *L. monocytogenes* meningitis do not reveal bacteria. The CSF findings in an infant with a brain abscess may include a pleocytosis of up to a few hundred

cells, a predominance of mononuclear cells, and an elevated protein concentration. Bacteria may not be seen on a Gram-stained smear of CSF if meningitis is not present.

Ventriculitis may complicate neonatal bacterial meningitis.[10,18] Obstructive ventriculitis is suspected when the head circumference increases dramatically, the anterior fontanelle is persistently full, CSF cultures are persistently positive, and examination of ventricular fluid shows elevation of WBCs with polymorphonuclear predominance, presence of bacteria on Gram-stained smear, and positive culture. Brain imaging by cranial ultrasound, computed tomography (CT), or magnetic resonance imaging (MRI), with contrast material, may show enhancement of the lining tissue of the ventricles or brain abscess formation.

Ampicillin and gentamicin or cefotaxime, administered in meningeal doses, are recommended for initial empirical treatment of neonatal meningitis for most neonates. If there is an indwelling device, such as a ventricular-to-peritoneal shunt in place, or a Gram-stained smear shows gram-positive cocci, staphylococci should be suspected and vancomycin administered. All neonates with bacterial meningitis should undergo repeat CSF examination and culture 24 to 48 hours after initiation of therapy. If organisms are observed on Gram-stained smears of fluid or cultures are still positive, modification of the therapeutic regimen should be considered, and repeat CSF examination should be performed until sterility is documented.

In all neonates with bacterial meningitis caused by *Citrobacter diversus* or *Cronobacter (Enterobacter) sakazakii*, cranial CT or brain MRI imaging should be obtained early because of the frequent association with brain abscess. The duration of antibiotic therapy should be extended up to 6 weeks or more, depending on clinical evolution and resolution of the lesion based on repeated CT. A neurosurgeon should be consulted early for needle aspiration of the abscesses to determine identification and susceptibility pattern of the organism. Aminoglycosides probably should not be used because of decreased activity in abscess cavities that have low pH and anaerobic conditions.

Third-generation cephalosporins possess attractive features, including lower MICs for gram-negative enteric bacilli than with aminoglycosides, good penetration into CSF in the presence of inflamed meninges, and a wide therapeutic index, for the treatment of bacterial meningitis in newborn infants. These agents are active against most streptococci but inactive against *L. monocytogenes* and enterococci. Only ceftazidime provides adequate activity against *Pseudomonas aeruginosa*. Among these agents, cefotaxime is preferred for the treatment of neonatal meningitis caused by susceptible gram-negative organisms, because of extensive experience with this drug in the neonatal period and because it does not alter the bowel flora substantially. Cefotaxime can be used singly or in combination with an aminoglycoside. Ceftazidime has been shown to be effective in treating patients with *P. aeruginosa* meningitis. Because of high biliary excretion and marked alteration of the normal intestinal flora and because of potential concern for displacement of bilirubin, routine use of ceftriaxone during the neonatal period is not recommended by most experts. After the pathogen has been identified and susceptibility studies are available, the single drug or combination of drugs that is most effective should be used. When MRSA or *S. epidermidis* is the cause of infection, vancomycin and amikacin or cefotaxime can be used initially, possibly with addition of rifampin systemically. Imipenem, meropenem, cefepime, and ciprofloxacin have been used to successfully treat neonatal meningitis caused by multiresistant gram-negative bacteria. For neonatal meningitis caused by *Flavobacterium meningosepticum* isolates, combined use of parenteral vancomycin and rifampin has been suggested as the best therapeutic option.

In general, penicillin G or ampicillin is preferred for GBS meningitis, ampicillin for *L. monocytogenes* and enterococci, ampicillin plus an aminoglycoside or cefotaxime for coliforms, and ceftazidime or ticarcillin-clavulanate and an aminoglycoside for *Pseudomonas* infections. The duration of systemic therapy in neonatal meningitis depends on the causative agent and the time necessary to sterilize CSF cultures. As a rule, therapy is given for approximately 2 weeks after bacteriologic cure has been achieved. For meningitis caused by GBS or *Listeria*, approximately 2 weeks of therapy usually is satisfactory. Because delayed sterilization is a common occurrence in infants with gram-negative enteric disease, systemic therapy is given for a minimum of 3 weeks and in some babies for many additional weeks. Final judgment about when to discontinue therapy must be based on the clinical course of the illness, CSF findings at the proposed end of treatment period, and brain imaging results to assess for abscess formation.

On the basis of the findings from the second Neonatal Meningitis Cooperative Study and summaries of recent clinical trials, intraventricular therapy cannot be recommended for the routine management of neonatal meningitis caused by gram-negative enteric bacilli.[3] However, on an individualized basis, intraventricular therapy may be of benefit in certain patients with obstructive ventriculitis caused by persistent or resistant organisms. The routine use of steroids in neonatal meningitis cannot be recommended. A prospective trial found lack of effectiveness of dexamethasone for neonatal meningitis in terms of mortality and sequelae rates in contrast to the nonsteroid group. Because this study was small (not sufficient statistical power), not blinded, and without a placebo group, additional studies are required to determine whether dexamethasone has a beneficial effect in neonates with meningitis.

Acute complications of bacterial meningitis include communicating and noncommunicating hydrocephalus, subdural effusions (~1% of patients), deafness, and blindness. Ventriculitis occurs in approximately 70 percent of neonates with coliform meningitis and usually is detected at the time of initial diagnosis. Brain abscess is an infrequent complication, except in infants with *C. diversus* or *C. (E). sakazakii* meningitis, in whom abscess develops approximately 70 percent of the time. A 30 to 50 percent incidence in neurologic sequelae has been reported in surviving infants. Although neurologic deficits may be obvious in some infants at discharge, most

babies appear "well" at this time. Only after prolonged and careful follow-up do the perceptual difficulties, behavioral problems, and other subtle neurologic signs become apparent. Within 4 to 6 weeks of recovering from meningitis, hearing should be evaluated by evoked response audiometry.

Case-fatality rates in neonates with meningitis range from 15 to greater than 30 percent.[17] A mortality rate of 30 percent was observed in 117 neonates with coliform meningitis enrolled in the first Neonatal Meningitis Cooperative Study. In this project, term infants had a significantly lower rate (18%) than that observed in low-birth-weight (<2500 g) babies (45%) and in infants older than 30 days (48%). Poor outcome after gram-negative enteric meningitis is correlated directly with the presence of ventriculitis, the persistence of positive CSF cultures, the presence and persistence of elevated endotoxin and interleukin-1β concentrations in CSF, a CSF cell count of greater than 10,000/mm^3, and a CSF protein concentration higher than 500 mg/dL. When meningitis is caused by *E. coli* K1, poor outcome is associated with persistence of large quantities of K1 capsular polysaccharide antigen in CSF.

Long-term follow-up studies of babies with coliform meningitis enrolled in the Neonatal Meningitis Cooperative Study have revealed that approximately 65 percent of survivors were normal 3 to 7 years after illness. An additional 30 percent were classified as having mild to moderate neurologic sequelae. Many of these latter patients had only slightly abnormal neurologic or psychological evaluations and were considered normal on routine physical examination. About 5 to 10 percent of survivors had severe neurologic or mental impairment requiring custodial care. Approximately 15 to 20 percent of survivors of GBS meningitis have major sequelae, including spastic quadriplegia, profound intellectual disabilities, hemiparesis, deafness, and blindness. Hydrocephalus develops in 11 percent, and 13 percent have a seizure disorder. The survivors without major sequelae on physical examination, however, appear to function within normal limits and comparably to their siblings. Experience with gram-negative enteric bacillary meningitis reported in 98 identified neonates managed from 1969 through 1989 revealed a case-fatality rate of 17 percent; 61 percent of survivors had long-term sequelae that included seizure disorders, hydrocephalus, physical disability, developmental delay, and hearing loss.

The outcomes for GBS meningitis have been reported. A 21 percent morbidity rate after GBS meningitis has been reported in one study. Of the survivors, 29 percent had severe neurologic sequelae, 21 percent had minor deficits, and 50 percent were functioning normally. Factors at initial evaluation associated with death or severe disability included coma, decreased perfusion, CSF protein greater than 300 mg/dL, an absolute neutrophil count of less than 1000, and a total leukocyte count of less than 5000/mm^3. A report from Canada noted that duration of seizures longer than 72 hours, presence of coma, use of inotropes, and leukopenia were the most important predictors of an adverse outcome.

Otitis Media

Otitis media is diagnosed infrequently in neonates because of the paucity of clinical findings and the difficulty of examining an infant's tympanic membrane. The external canal is narrow and tortuous and often is filled with debris. Because a healthy baby's membrane may appear thickened and dull, mobility of the drum determined by pneumatoscopy should be used as the single most reliable indicator of middle ear abnormalities.

Otitis media develops more commonly in premature than in term infants and occurs more often in bottle-fed babies. It is a frequent finding in neonates receiving intensive care, especially those with prolonged nasotracheal intubation. Meconium staining of amniotic fluid and prolonged rupture of membranes are two other risk factors for the subsequent development of middle ear disease. Neonates with cleft palate, Down syndrome, or maxillofacial anomalies are at high risk for the development of chronic middle ear disease. The onset of illness associated with otitis media is insidious, and the most common manifestations are rhinorrhea, irritability, and failure to thrive. Fever higher than 38°C (100.4°F) is a rare finding. The presence of lethargy, hypotonia, hypothermia, high fever, or jaundice suggests the otitis media is complicated by bacteremia or meningitis.

The cause of neonatal otitis media is similar to that observed in older infants and children. *S. pneumoniae*, *H. influenzae*, and *Moraxella catarrhalis* account for more than 50 percent of cases. Approximately 10 to 15 percent of neonates have disease caused by coliforms, GBS, or *S. aureus*. Therefore, antibiotics that include those organisms in their spectrum of activity (i.e., second-generation cephalosporin or amoxicillin-clavulanate) may be preferable to the aminopenicillins for outpatient management of the neonate who otherwise appears well. The patient's condition should be reevaluated 8 to 72 hours after therapy is initiated to determine whether clinical improvement has occurred and whether the middle ear infection is resolving or if systemic disease is present. In patients demonstrating no improvement, tympanocentesis should be performed for examination of stained smears of middle ear fluid and for culture of the contents. Changes in therapy should be based on the findings of these examinations. If gram-negative organisms or staphylococci are observed, or if the neonate appears ill, the infant probably is managed best in the hospital with administration of parenteral antibiotics such as ampicillin and an aminoglycoside if coliforms are suspected or an antistaphylococcal penicillin or vancomycin for *S. aureus*.

Diarrheal Disease

Diarrhea can be a nonspecific symptom of sepsis or urinary tract infection in a newborn infant. Bacteria that may cause diarrhea in the neonate include enteropathogenic *E. coli*, *Vibrio cholerae*, some *E. coli* nonenteropathogenic strains, *Vibrio parahaemolyticus*, *Aeromonas*, *Shigella*, *Salmonella*, *Campylobacter*, and *Yersinia*. Some

diarrheal episodes in neonates probably can be caused by *Clostridium difficile* and may be a presenting symptom for Hirschsprung disease.

Although the cause of diarrhea in infants and children may be suspected on clinical grounds, usually this is not possible in newborn infants. As a general rule, diarrhea caused by enteropathogenic strains of *E. coli* is insidious in onset, is associated with 7 to 10 green watery stools daily, and generally is without blood or mucus. These infants do not appear to be acutely ill. Complications rarely occur and primarily are related to dehydration and electrolyte disturbances. Shigellosis in a newborn may occur as a diarrheic or dysenteric syndrome or may be evidenced only by a septic- or toxic-appearing infant. Suppurative complications are rare events, but dehydration and electrolyte disturbances are common and need immediate and constant attention. *Salmonella*, on the other hand, may cause sepsis and bacterial meningitis in the neonate. *Campylobacter jejuni* infection typically involves the gastrointestinal tract and produces watery diarrhea or a dysentery-like illness with fever and bloody mucoid stools. Extraintestinal infections related to *C. jejuni*, other than bacteremia, are rare occurrences but include cholecystitis, urinary tract infection, and meningitis. The clinical manifestations in neonates with *Campylobacter fetus* infection are similar to those caused by the common neonatal pathogens. *C. jejuni* has been reported to cause bloody diarrhea in otherwise asymptomatic neonates.

The most important aspect of therapy for diarrheal disease of newborn infants is maintenance of hydration and electrolyte balance. As a rule, oral or parenteral solutions containing appropriate electrolytes should be administered during the time of active diarrhea, and the infant should be examined and weighed frequently to ensure proper rehydration has been achieved and prevent the development of complications. Estimates of fluid loss from diarrhea and vomiting should be recorded carefully and used as a basis for replacement therapy.

Neonates and infants younger than 3 months with diarrhea caused by *Salmonella* should be carefully evaluated for systemic illness and treated with antibiotics. Neonates with shigellosis, more common in developing countries, also should receive orally administered antibiotics if the neonate otherwise appears well. Erythromycin, or other macrolides, is the preferred drug for treating symptomatic *C. jejuni* enteritis. Frequently, if erythromycin therapy is initiated within the first 4 days of illness, excretion of the organism is reduced and symptoms resolve rapidly. An aminoglycoside is the drug of choice for treating *C. fetus* infections; chloramphenicol is an alternative in developing countries.

Any infant with diarrhea must be isolated from other babies in the nursery. Surveillance of all infants in contact with the index case and institution of infection control measures are recommended.

Probiotics and synbiotics (generally strains of *Bifidobacterium*, *Lactobacillus*, or *Saccharomyces*) have been used for the prevention and treatment of acute gastroenteritis and neonatal sepsis with beneficial results, and their use in neonates remains under investigation.

Urinary Tract Infections

The incidence of bacteriuria and urinary tract infection in newborn infants ranges from 0.5 to 1 percent for term infants and is approximately 3 percent for premature infants. Most infants with significant bacteriuria are asymptomatic or have nonspecific signs and symptoms. The neonate may appear septic or may have decreased activity, feeding problems, and the other constitutional signs that are seen with infections of other organ systems. Jaundice, hepatomegaly, and thrombocytopenia may be observed in a few infants with urinary tract infection; these findings are associated with septicemia or cholestatic hepatitis in some babies. Localizing signs suggesting urinary tract involvement are unusual findings. When present, they usually consist of a weak urinary stream on voiding or an abdominal tumor from bladder distention, hydronephrosis, or both.

E. coli is the most common etiologic agent of urinary tract infections and accounts for approximately 90 percent of acute infections and 70 to 80 percent of recurrent disease. *Proteus*, *Klebsiella*, and *Pseudomonas* spp. are usually encountered in patients with recurrent disease, particularly those receiving prolonged antimicrobial prophylaxis. Gram-positive bacteria, with the exception of enterococci, rarely are encountered as pathogens for the urinary tract. Only a few neonatal cases of renal abscess have been reported in the literature. *S. aureus* and coliforms were the predominant etiologic agents.

The diagnosis of urinary tract infection is confirmed by examination and culture of urine. The results of these tests depend largely on the method of urine collection. Most pediatricians obtain urine with a sterile, plastic receptacle applied to the cleansed perineum. However, urine obtained by this method may have an elevated cell count because of recent circumcision, vaginal reflux of urine, or contamination from the perineum. Neonatal asphyxia also may increase the urine cell count. WBCs must be differentiated from round epithelial cells, which appear in the urine in significant numbers during the early days of life. Although pyuria commonly accompanies significant bacteriuria, cells can be few or absent. Direct microscopic examination of uncentrifuged, fresh urine is useful. If bacteria are seen readily in each high-power field, they generally number greater than 10^5 cells/mL.

Quantitative urine cultures from infants with documented disease usually contain more than 100,000 colonies/mL of a single bacterial species. Any number of bacteria in a urine specimen obtained by percutaneous needle puncture of the bladder should be considered significant. The procedure should not be performed in infants who are dehydrated, are distended, have abnormal bladder or urinary system anatomy, or have bleeding problems. If a "bagged urine specimen" contains fewer than 100,000 colonies/mL of a single species of bacteria or if the culture yields a mixed bacterial population, a repeat urine specimen should be obtained by suprapubic bladder aspiration or catheterization for culture.

Blood and urine should be obtained for culture from all newborn infants with suspected or proved urinary tract infection before antimicrobial therapy is initiated.

Antibiotics initially are administered parenterally because sepsis is associated with urinary tract infection in 20 to 30 percent of infants and absorption of antibiotics after oral administration is erratic in some babies. Therapy should be initiated with an aminoglycoside and ampicillin in most neonates to provide antibacterial coverage for the anticipated coliforms, enterococci, and GBS. If the patient has renal impairment, ampicillin and cefotaxime constitute an alternative empirical regimen.

A repeat urine culture performed 48 to 72 hours after initiation of appropriate therapy should be sterile or show a substantial reduction in the bacterial count. Infants with persistent bacteriuria should be evaluated for the possibility of resistant organism, obstruction, or perinephric abscess. In uncomplicated disease, therapy usually is continued for a period of 7 to 10 days. Approximately 1 week after discontinuance of therapy, a repeat urine culture is performed.

Neonates with documented infection should undergo radiologic evaluation of the urinary tract. Renal sonogram may be performed to evaluate the possibility of gross congenital abnormalities of the urinary system. Congenital malformations are unusual findings in the fetus or in the first week of life in the neonate, but may be present in a significant proportion of infants with urinary tract infections after this age. If obstruction is demonstrated, urologic procedures to ensure proper drainage are mandatory if therapy is to be successful. Infants found to have anatomic abnormalities (e.g., significant vesicoureteral reflux) may be protected, for a period of time, from reinfection by prophylactic suppressive administration of antibiotics. Routine circumcision of the newborn protects against urinary tract infections during early infancy.

Suppurative Arthritis and Osteomyelitis

Osteomyelitis and suppurative arthritis are unusual in the first 4 weeks of life. Bone and joint infections can be difficult to detect in neonates and young infants. Early establishment of the diagnosis and appropriate management are important steps to reduce orthopedic abnormalities later in life.

The infecting organisms in osteomyelitis and septic arthritis vary, but the predominant ones are *S. aureus* (both MSSA and MRSA), GBS, and gram-negative enteric organisms such as *Klebsiella*, *Proteus*, and *E. coli*. Gonococcal arthritis and tenosynovitis were common occurrences in neonates in previous decades and still may be seen in developing countries. Other bacteria associated infrequently with newborn infection in the bones and joints are *Salmonella* and *Pseudomonas*.

Osteomyelitis and arthritis have been reported in newborns after several invasive procedures, including heel puncture, femoral venipuncture, exchange transfusions, fetal monitoring with electrodes, serial lumbar puncture, and umbilical artery catheterization. Osteomyelitis of cranial bones has complicated infected cephalohematomas. The use of peripheral and central intravascular catheters in neonates has been associated with the development of bacterial osteomyelitis. Septic embolization from catheter tip thrombi, together with local hypoxia from partial occlusion of the vessel by the catheter, may explain this association. During the infant's first month of life, the epiphyseal plate is traversed by multiple small transepiphyseal vessels that provide direct communication between the articular space and the metaphysis of the long bones. As a result, infection of the metaphysis (i.e., osteomyelitis) can spread across the growth plate and penetrate the epiphysis or enter the joint space. The large vascular spaces and thin spongy structure of the metaphyseal cortex in infants permit early decompression of the primary abscess into the subperiosteal space. The abscess then dissects rapidly between the loosely attached periosteum. As pressure increases from the accumulating pus, a subcutaneous abscess can develop that may point and drain spontaneously through the skin and form a sinus tract.

Two distinct clinical syndromes that may be associated with osteomyelitis in the newborn period have been described. The first form presents as a local infection, in which the earliest sign of bone and joint infection in newborns is failure to move an extremity spontaneously or apparent pain on movement without systemic evidence of infection. Swelling, erythema, and heat localized to the affected part are late findings. Multiple bones or joints can be involved, especially when disease is caused by *S. aureus*. The second form of presentation is characterized by disseminated, systemic manifestations of sepsis; only later are multiple sites of bone and visceral involvement noted.

Another unique clinical presentation of osteomyelitis in the newborn is maxillary bone involvement by osteomyelitis, usually caused by GBS or *S. aureus*. Maxillitis or osteomyelitis of the superior maxilla is an unusual form of bone infection in newborn infants. More than 85 percent of all maxillary infections in infants take place in the first 3 months of life, with the peak incidence occurring in the second to fourth weeks. Swelling of the cheek, associated with unilateral nasal discharge of pus, and swelling of the alveolar ridge of the maxilla should alert the physician to this entity.

Conventional radiography may establish the diagnosis in patients with suspected suppurative arthritis; radiographs may be normal or show enlargement of the joint space. Later in the course of disease, subluxation and destruction of the joint are common findings. In early osteomyelitis, the normal radiographic water markings of tissues adjacent to the affected bone may be obliterated, because of deep-tissue inflammation and swelling. Lifting of the periosteum also may be observed, but cortical bone destruction seldom occurs before the second week of illness. A complete skeletal survey should be performed because of the frequent involvement of multiple sites in neonates, especially if bacteremia or sepsis is present. MRI also is recommended for establishing the diagnosis of osteomyelitis in the newborn period.

Blood should be obtained for culture from all infants with osteomyelitis or septic arthritis. A recommended sample is percutaneous needle aspiration of intra-articular pus in patients with suspected suppurative arthritis or aspiration of sequestrum or abscess or lytic bone lesion in those with suspected osteomyelitis. If pus or tissue is obtained, the material should be Gram stained and cultured.

Selection of initial antimicrobial therapy is guided by preliminary identification of the pathogen from stained smears of material obtained by needle aspiration. If no microorganisms are seen, initiating treatment with two drugs, a penicillinase-resistant penicillin (e.g., nafcillin) for treatment of *S. aureus*, and cefotaxime, to provide treatment for both enteric gram-negative organisms and GBS, is advisable. Vancomycin should be added initially, if MRSA is a possibility.

Surgical removal of infected material is an integral part of treatment, even in the neonate. Open drainage is essential for managing septic hip disease. The inflammation in osteomyelitis or septic arthritis can occupy the epiphyseal and metaphyseal sides of the growth plate and result in ischemia and necrosis of the plate and permanent orthopedic damage. For other joints, repeated daily evacuation of fluid with a needle and syringe usually is adequate. In patients with osteomyelitis, the subperiosteal space and the metaphysis should be drained if pus is obtained during diagnostic aspiration. If only a small amount of bloody material is obtained at aspiration, surgery does not need to be performed immediately and the patient generally can be managed with antibiotic therapy alone as long as the local and systemic signs resolve. If improvement is unsatisfactory, repeat aspiration or open surgical drainage may need to be performed.

Antimicrobial treatment of neonatal musculoskeletal infections caused by *S. aureus* or gram-negative organisms is continued for a minimum of 4 to 6 weeks, depending on clinical response. Intravenous treatment may be followed by long-term suppressive treatment in patients with complicated, recurrent, or chronic bone disease. GBS infection of bones and joints is usually treated with penicillin G or ampicillin for at least 2 weeks, longer in complicated cases. Ten days of treatment usually is adequate for treatment of gonococcal disease of the bones or joints in most neonates.

Conjunctivitis and Orbital Cellulitis

Infections of the eye of the newborn can be caused by a variety of microorganisms, including *Neisseria gonorrhoeae*, *Chlamydia trachomatis*, *S. aureus* (MSSA or MRSA), and *P. aeruginosa*. Other less frequently encountered organisms included *M. catarrhalis*, *Pasteurella multocida*, and *Neisseria meningitides*. Nonbacterial organisms, including *Chlamydia* and herpes simplex virus, should be considered in the differential diagnosis of neonatal conjunctivitis. Any infant with a conjunctival discharge should be evaluated carefully to determine the cause. Three tests should be performed: Gram and methylene blue stain of the exudate, culture of the exudate, and Giemsa stain and culture for *Chlamydia*, if available, of scrapings made from the lower palpebral conjunctiva after the exudate has been removed. The results of the stained smears and cultures determine the appropriate therapy.

Funisitis and Omphalitis

If inflammation of the cord alone is present, funisitis is diagnosed. It is characterized by wet, malodorous umbilical cord and stump, without surrounding cellulitis. The umbilical cord may be colonized with numerous different potential bacterial pathogens, some of which, like GAS, may not only cause inflammation in the cord of the neonate but also produce nursery outbreaks of disease.

Omphalitis, or infection of the umbilicus, has many causes and occurs more frequently in low-birth-weight infants and those with complicated deliveries. The incidence is estimated to be approximately 2 percent, and symptoms start at an average age of 3 days. Culture and susceptibility test results are necessary for the selection of an appropriate antibiotic. *S. aureus* is the most frequent pathogen isolated, followed by GAS, GBS, and gram-negative rods. Some of the complications secondary to omphalitis reported in the literature are bacterial sepsis, spontaneous evisceration of the small bowel through the umbilical cicatrix, necrotizing fasciitis, small bowel obstruction, peritonitis, and superficial, retroperitoneal, or hepatic abscesses.

Breast Abscess

Breast abscesses are encountered most frequently during the second or third week of life and are more common findings in girls, particularly those older than 2 weeks. The disease does not appear to occur in premature infants, presumably because of underdevelopment of the mammary glands in these infants. Bilateral disease is a rare event.

The major clinical finding is swelling of the affected breast with or without accompanying erythema and warmth. Systemic manifestations are uncommon occurrences, and only a fourth of patients have low-grade fever. The disease sometimes can progress rapidly and involve breast tissue and the entire subcutaneous tissue beyond the breast's anatomic area. This condition is associated with considerable toxicity and systemic signs and symptoms. *S. aureus* is the major pathogen, but coliform bacteria, such as *E. coli* and *Salmonella*, and GBS have become more common causes in the past decade. Mixed infection rarely occurs. Breast abscess is diagnosed by examination of stained purulent material obtained from gentle manipulation of the nipple or by needle aspiration of the abscess. If gram-positive cocci are identified, nafcillin or another penicillinase-resistant penicillin is administered. For gram-negative bacilli, an aminoglycoside or cefotaxime is appropriate. When no organisms are seen, nafcillin and an aminoglycoside or cefotaxime should be used initially until results of culture are available. Blood cultures should be obtained, but bacteremia is a rare finding in this condition. If the patient has only mild cellulitis and no discernible fluctuance, antibiotic treatment alone may suffice. Fluctuant abscesses should be drained.

Suppurative Parotitis

Suppurative parotitis of the newborn usually is easy to recognize, although occasionally it is confused with infection of a preauricular or superior anterior cervical lymph node. Infection occurs more commonly in low-birth-weight infants than term infants and in boys.

Dehydration predisposes to stasis of parotid secretions and subsequent infection. Bilateral infection is a rare event.

Although *S. aureus* (MSSA and MRSA) accounts for most cases, disease may be caused by coliform bacteria, *Pseudomonas*, pneumococci, and GAS. The clinical manifestations include fever, anorexia, irritability, and failure to gain weight. Erythema, swelling, and tenderness over the involved gland may occur. The diagnosis can be confirmed by expressing pus through the parotid duct or by needle aspiration of a fluctuant area. Gram staining of this material helps identify the causative agent. Selection of antimicrobial therapy should be based on interpretation of the Gram-stained smear of expressed pus. If gram-positive cocci are seen, nafcillin or another penicillinase-resistant penicillin should be used. Vancomycin should be added if MRSA is a possibility. Gram-negative organisms are treated best with an aminoglycoside, cefotaxime, or ceftazidime to cover both coliform bacteria and *Pseudomonas*. If no organisms are seen in the purulent material, a combination of nafcillin and gentamicin or cefotaxime should be used until the results of culture are available. In most cases, antibiotic therapy alone suffices, and surgical incision and drainage are unnecessary. The gland should not be extirpated. Response to therapy generally is rapid. Most patients require only 7 to 10 days of therapy until healing is complete.

Scalp Abscess

Scalp abscesses usually are a complication of fetal monitoring with scalp electrodes. The number of vaginal examinations, use of more than one electrode, and fetal scalp blood sampling are risk factors for the development of scalp abscesses. Pathogens incriminated include staphylococci, gonococci, and gram-negative enteric bacteria. A polymicrobial flora, including anaerobic organisms, frequently is isolated in scalp abscesses caused by electronic fetal monitoring electrodes. Incision and drainage of the infected site along with antibiotics for 7 days usually is sufficient for most term neonates with uncomplicated scalp abscesses caused by susceptible bacteria. Scalp lesions associated with scalp electrodes that do not show bacteria on Gram stain or culture may be caused by herpes simplex virus, and should be evaluated with viral culture of lesions and surfaces, examined by HSV DNA PCR of blood and CSF, and treated with intravenous acyclovir.

Pneumonia

Neonatal lower respiratory tract bacterial infections may be acquired congenitally or postnatally. Congenital or perinatal infection results from transplacental transfer of the agent (i.e., congenital infection) or from inhalation of infected amniotic fluid (usually associated with prolonged rupture of membranes) or infected vaginal secretions during delivery.

Common bacterial pathogens causing postnatally acquired pneumonia are *S. aureus*, coliform bacilli, and *Pseudomonas*. These infections occur sporadically or epidemically and may be acquired from the community in otherwise healthy neonates or health care associated in hospitalized neonates. They may be rapidly progressive, necrotic pneumonias that result in pyogenic complications (e.g., empyema and pulmonary abscesses) and metastatic disease to the bones or meninges. The early signs of respiratory disease in neonates frequently are nonspecific and include change in feeding status, listlessness or irritability, and poor color. More specific findings that may not be present at the onset of illness are tachypnea, dyspnea, cyanosis, alteration of temperature (i.e., hypothermia or fever), coughing, and grunting. Accentuation of the normal irregularity of breathing and "head bobbing" also may be present.

The physical findings of pneumonia are variable. Flaring of the alae nasi, rapid respirations, and sternal and subcostal retractions are common findings. Coughing indicates lower respiratory tract involvement; brassy coughing is found frequently in viral disease. Dullness to percussion is difficult to demonstrate, but when present, it indicates consolidation or effusion. Breath sounds also may be diminished over the affected area. Crackles or wheezes usually can be heard on deep inspiration (or when the baby is crying) but may be absent early in disease. The clinician frequently is surprised by the meager clinical signs in the face of clearly demonstrable and sometimes extensive radiographic findings of pneumonitis.

Cultures of blood and material from the trachea frequently help in defining the etiologic agent of neonatal pneumonia. A chest radiograph should be obtained for all babies with suspected lower respiratory tract disease. Radiographic evidence of pneumonia may exist in the absence of specific physical findings. Although the cause of neonatal pneumonia usually can be determined from a radiograph, certain radiologic patterns are associated with specific diseases. With acute-onset GBS disease, the radiograph may mimic one showing hyaline membrane disease. A consolidating bronchopneumonia with pneumatoceles, with or without empyema, suggests staphylococcal disease. When a lobar infiltrate is associated with expansion of the lobe, *K. pneumoniae* infection should be considered. A miliary type of bronchopneumonia in a septic neonate is characteristic of listeriosis or, less commonly, mycobacterial disease.

Pertussis is also an important cause of respiratory disease and pneumonia in the neonate. The onset of disease generally is in the second to sixth weeks of life; the earliest onset reported was at 10 days of age. Most young infants do not have a characteristic whoop. Pertussis should be suspected when an infant has a paroxysmal cough with excessive mucus. Because apneic spells are common occurrences in these infants, all infants with pertussis are admitted to the hospital for management. PCR-based methods are currently recommended, as well as fluorescent antibody testing, to confirm the diagnosis. The greatest hazards to an infant with pertussis are asphyxia and secondary bacterial pneumonia. Supportive care is essential. Excessive mucus must be suctioned, and equipment for emergency airway intubation should be at hand. Administration of fluid therapy is necessary, and maintaining adequate nutritional intake may present

the greatest challenge. Infants with pertussis should not be placed in mist tents. Mist therapy provides no substantial amelioration of paroxysmal coughing episodes, and it increases the risk for development of secondary infection with *P. aeruginosa* (or with other commensals). Atelectasis caused by mucus plugs is a common complication of pertussis in small babies. After the infant has passed the stage of severe paroxysms, chest physiotherapy can be initiated. In almost all cases the atelectasis resolves within 2 to 3 weeks.

Initial antibiotic treatment of suspected bacterial pneumonia should consist of ampicillin or nafcillin or vancomycin and an aminoglycoside or cefotaxime. The most suitable combination of these drugs depends on the clinical features of the illness and the recent experience with bacterial diseases in the local nursery or community. For patients in whom the cause never is defined and staphylococcal disease cannot be ruled out, therapy with nafcillin or vancomycin and an aminoglycoside or cefotaxime is indicated. If the organism is identified, the single most effective drug should be used. Penicillin G or ampicillin is effective against GBS and penicillin-susceptible staphylococci, ampicillin against *Listeria*, and nafcillin or another suitable antistaphylococcal penicillin against penicillinase-producing *S. aureus.* Vancomycin should be used for disease caused by MRSA or coagulase-negative staphylococci. For pneumonia caused by gram-negative bacilli (e.g., *K. pneumoniae* and others), an aminoglycoside or a third-generation cephalosporin should be used. *Pseudomonas* pneumonia is treated best with ticarcillin or ceftazidime in combination, sometimes also with an aminoglycoside. Therapy is continued for 10 to 14 days for disease caused by GBS and *Listeria* and for a minimum of 3 weeks for pneumonia caused by staphylococci or gram-negative bacilli.

Health care–associated or ventilator-associated pneumonia may occur in mechanically ventilated premature infants and can be caused by a vast array of microorganisms. Accordingly, treatment with an empirical regimen of broad-spectrum antibiotics is advised until microbial identification is made. Nonetheless, the physician should realize that isolation of bacteria from tracheal aspirates usually represents airway colonization and not necessarily the etiologic agents. For a reliable etiologic approach, a combination of clinical, radiographic, laboratory, and microbiologic findings is recommended. An important matter to recognize is that antimicrobial therapy commonly fails to eradicate colonizing microorganisms from the airway of ventilated infants despite clinical and radiographic resolution of pneumonia.

Empyema is managed best by closed drainage and use of chest tubes with the largest possible caliber. Generally, placement of one tube high and anteriorly and a second tube low and posterolaterally is necessary to achieve optimal drainage. Pyopneumothorax is another indication for immediate insertion of a catheter into the pleural space. After the infant has improved clinically and the amount of drainage is minimal, the tubes should be removed. In general, they should not remain in the chest for more than 5 to 7 days. Therapy for pertussis consists of azithromycin or erythromycin administered orally or intravenously. Antibiotic therapy may lessen the symptoms of pertussis if administered early in the paroxysmal stage and is valuable for rendering the patient noncontagious. Associations between bronchopulmonary dysplasia and respiratory colonization by *U. urealyticum*, *C. trachomatis*, *Mycoplasma hominis*, and adenovirus have been shown in different studies.

YEAST AND FUNGAL INFECTIONS OF THE FETUS AND NEONATE

The improved survival of preterm infants since the early 1980s has resulted in the emergence of yeasts and fungi as significant neonatal pathogens. *C. albicans* remains the most frequently isolated pathogenic yeast overall, but other *Candida* spp., especially *Candida parapsilosis* and *Candida tropicalis*, and less common pathogenic yeasts, such as *Malassezia*, *Trichosporon*, *Rhodotorula*, and *Pichia* (formerly *Hansenula*), have increased in frequency. The incidence of invasive fungal disease, often with fatal outcomes, caused by *Aspergillus* and Zygomycetes (*Mucor*; *Rhizopus*, *Rhizomucor*; and *Absidia*) also has increased in neonates, especially infants who were born premature or with an inherited metabolic disorder or primary immunodeficiency.

Neonatal Candidiasis

Candida spp. account for approximately 9 percent of all health care–associated infections in the neonatal intensive care unit (NICU). *Candida* spp. infect approximately 1 to 6 percent of infants with a birth weight less than 1500 g (very low birth weight [VLBW]) and 5 to 10 percent of infants with a birth weight less than 1000 g (extremely low birth weight [ELBW]) (Fig. 66-2).

The species isolated most frequently from neonates is *C. albicans*, which represents approximately 40 to 60 percent of isolates from neonates with systemic disease and is the most common *Candida* spp. associated with NICU outbreaks.[19] *Candida* spp. other than *C. albicans* have become increasingly more prevalent, however, and in some NICUs may be isolated more frequently than *C. albicans*. Among these organisms, *C. parapsilosis* is the most common, followed by *C. tropicalis;* both of them have caused outbreaks in NICUs. *Candida glabrata*, *Candida guilliermondii*, *Candida lusitaniae*, and *Candida krusei* also have caused invasive disease in neonates. Most recently, *Candida haemulonii* has emerged as a neonatal pathogen and caused an outbreak in an NICU. Several risk factors consistently have been associated with systemic candidiasis, the most common being prematurity and VLBW and ELBW, with attendant impairment of host defense mechanisms; indwelling intravenous catheters; and prolonged use of broad-spectrum antimicrobial therapy, in particular, third-generation cephalosporins, which suppress normal gastrointestinal flora. Neonatal candidiasis may be congenital or acquired and ranges from commonly encountered benign oral and cutaneous candidiasis to systemic infection with candidemia to more severe and often fatal disseminated candidiasis.

Oral candidiasis is the most common form of infection with *Candida* spp. Lesions on the mucous membranes of

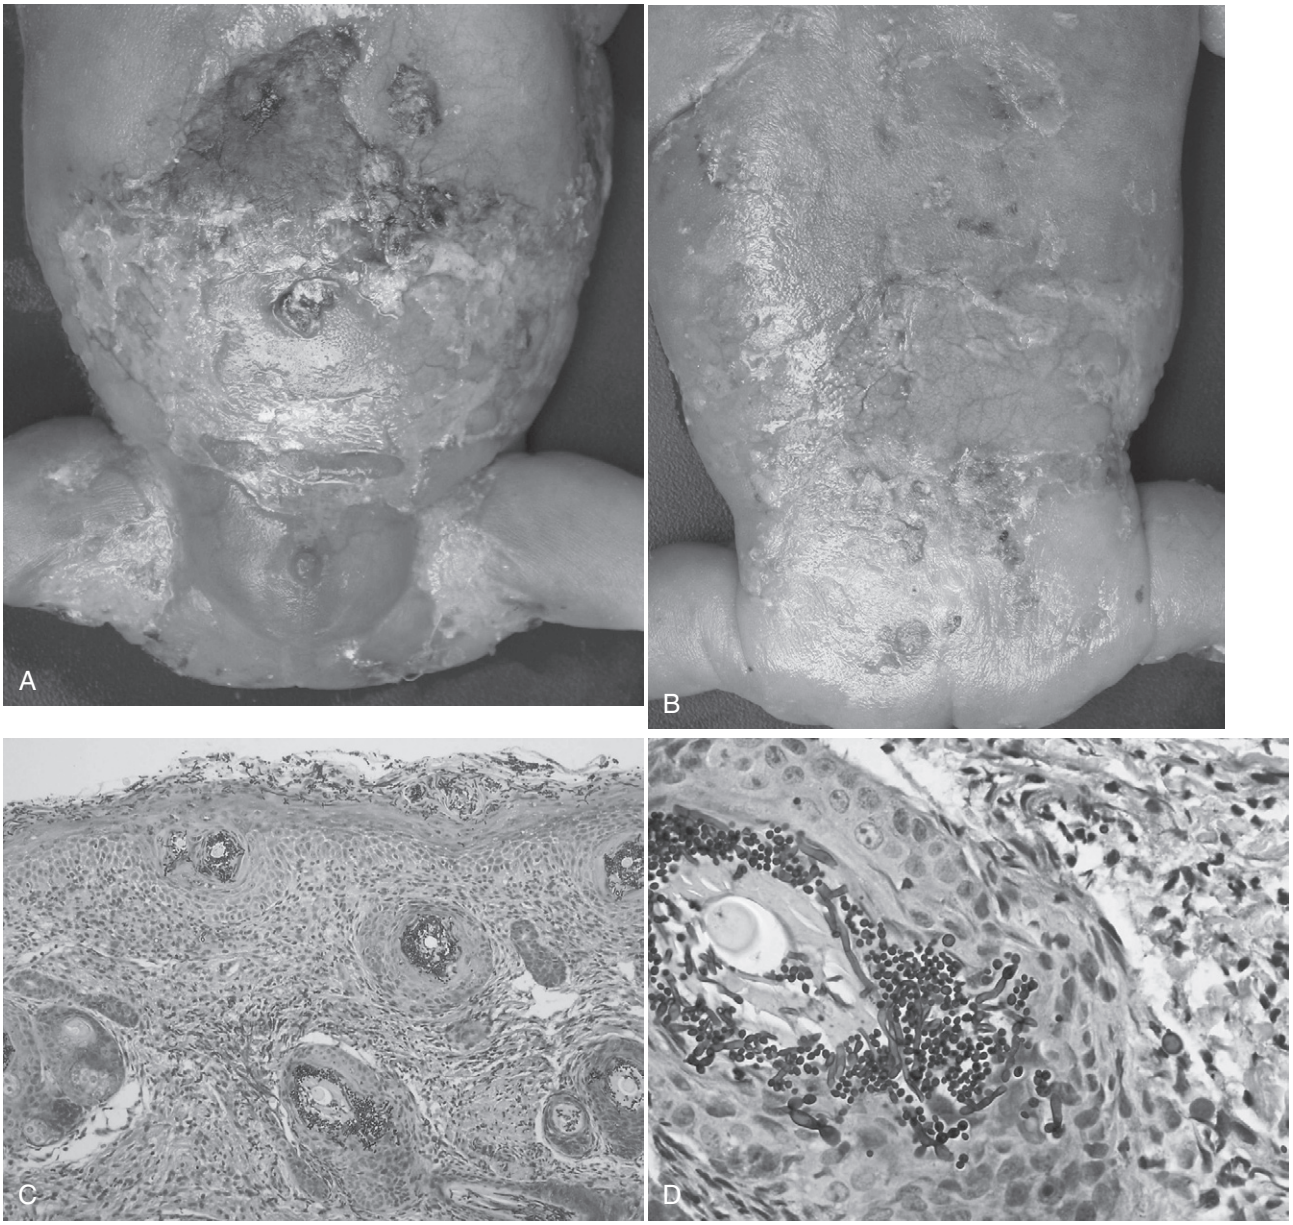

FIGURE 66-2 ■ Invasive cutaneous candidiasis. A 3-week-old, former 24-$\frac{2}{7}$ weeks of gestation premature infant with fatal invasive candidiasis. The skin on the abdomen **(A)** and back **(B)** showed extensive cutaneous ulceration and exudates caused by *Candida* infection. Autopsy examination showed disseminated candidiasis with thromboemboli, infarction, and microabscesses involving the brain, lungs, and kidneys. Skin biopsy specimen showed numerous ovoid yeasts and pseudohyphae infiltrating the stratum corneum and within hair follicles (periodic acid–Schiff stain, 100× original magnification) **(C)** and infiltration of yeasts deep into the dermal connective tissue (periodic acid–Schiff stain, 400× original magnification) **(D).** (Courtesy Dr. Megan K. Dishop, Department of Pathology, Baylor College of Medicine and Texas Children's Hospital, Houston, Tex.)

the mouth and oropharynx usually appear on the 7th to 10th day of life as whitish-gray plaques that can be scraped easily from the mucosa to expose an erythematous base. Persistent or recurrent infection may be caused by the continued use of bottle nipples and pacifiers that harbor *Candida* on their surface. Primary and acquired immunodeficiency states, including infection with HIV, should be considered if oral thrush fails to clear with appropriate therapy.

Cutaneous candidiasis typically is manifested by erythematous, vesiculopustular lesions found primarily on the skin of the perineum, axilla, and intertriginous areas. The periumbilical area also can be involved. Benign diaper dermatitis with so-called satellite lesions is a frequent occurrence in an otherwise healthy infant, and the peak incidence occurs at 3 to 4 months of age. In VLBW and ELBW premature infants, seemingly benign mucocutaneous lesions, including lesions in the perineum or diaper area, may progress rapidly to invasive dermatitis, producing cutaneous scales, crusting, erosions, ulcerations, or extensive maceration of skin, and result in a potentially lethal systemic candidiasis (see Fig. 66-2).

Scattered, faint, erythematous maculopapular lesions of the skin may be an expression of a serious disseminated candidiasis. Chronic mucocutaneous candidiasis may be diagnosed in an otherwise well-appearing infant, if *Candida* infections of the skin, mucous membranes, and nails persist or recur, despite administration of antifungal therapy. These neonates have a congenital defect in T-lymphocyte function specific to *Candida* spp.

Congenital candidiasis may cause fetal infection with onset of premature labor or intrauterine demise; it may be evident at birth, or it may appear within the first 24 to 48 hours of life. Term and preterm neonates may be affected. Maternal risk factors include a history during pregnancy of *Candida* vaginitis, use of antibiotics, retained intrauterine contraceptive device, cervical cerclage, and prolonged rupture of fetal membranes, although none of these factors may be present in the history. Poor prognostic factors for neonates include the presence of pneumonia or sepsis, prematurity, and early-onset neutropenia at presentation. Congenital candidiasis usually is caused by *C. albicans*, but other *Candida* spp., including *C. tropicalis* and *C. glabrata*, also have been reported to cause congenital candidiasis. Congenital cutaneous candidiasis most often manifests as a widespread, mucocutaneous infection, with erythematous maculopapular or vesiculopustular rash. Congenital pneumonia also may be a part of the disease, with or without the mucocutaneous or systemic signs. Congenital systemic candidiasis may manifest as life-threatening, early-onset sepsis syndrome, especially in premature neonates with septic shock, pneumonia, or meningitis; it also may be accompanied by leukocytosis or neutropenia, or it may mimic congenital leukemia. Twins may be affected, sometimes with different *Candida* spp., manifestations, and outcomes for each twin. Prenatal diagnosis of intrauterine infection with *Candida* may be determined by amniocentesis. A presumptive diagnosis in a neonate can be made by identifying budding yeast organisms on potassium hydroxide preparations or Gram-stained smears of the pustular or vesicular skin lesions, blood buffy coat, or gastric fluid aspirate. Growth of *Candida* in culture provides confirmatory evidence. Term newborns with congenital candidiasis usually have infection limited to the skin, mucous membranes, lungs, or gastrointestinal tract; *Candida* rarely is isolated from blood or other sterile body sites. In contrast, premature neonates with congenital candidiasis often have more severe disease, with positive blood cultures and evidence of disseminated disease, including meningitis. The umbilical cord from a fetus or newborn with congenital candidiasis may show *Candida* funisitis with yellow-white nodules and fungal microabscesses; the placenta also may have nodules and shows chorioamnionitis on histologic examination.

Acquired systemic candidiasis includes (1) catheter-associated sepsis, in which *Candida* is isolated from the blood of infants who have central venous catheters, but no evidence of focal infection or disseminated disease; (2) disseminated candidiasis, in which *Candida* is isolated from the bloodstream in association with other foci of infection, such as skin or intestine, regardless of whether the infant has a central venous catheter; and (3) focal disease of an organ, such as the lung or kidney or brain or disseminated disease caused by *Candida* spp., without a positive blood culture. No significant differences in presentation of systemic candidiasis caused by different *Candida* spp. have been apparent. The clinical and laboratory signs of systemic candidiasis usually are nonspecific and resemble signs seen with bacterial sepsis. Knowledge of prior colonization with *Candida* spp. or presence of cutaneous crusting or erosions, dermatitis, or skin maceration provides clinical clues that a sepsis syndrome in a premature neonate may be caused by invasive *Candida* spp. Signs and symptoms most commonly reported in neonates with systemic candidiasis include respiratory deterioration (74%), apnea and bradycardia (60%), carbohydrate intolerance (56%), skin manifestations (53%), abdominal distention (49%), temperature instability (35%), guaiac-positive stools (26%), and hypotension (21%). The sites most frequently involved in systemic neonatal candidiasis include the blood (60% to 80%), CNS (meningoencephalitis, 25% to 60%), lungs (pneumonia, 70%), kidneys (renal candidiasis, 60%), liver and spleen (19%), the eyes (endophthalmitis, 30%). End-organ disease is accompanied most often by positive blood or urine cultures, especially if cultures are persistently positive for more than 5 days. Not all neonates with end-organ disease with *Candida* spp. have positive blood or urine cultures, however.

The organ involved most frequently in systemic candidiasis seems to be the kidney. *Candida* may be isolated from the urine of 73 percent of neonates with systemic candidiasis with positive blood cultures, but only 5 to 15 percent of such neonates have documented *Candida* pyelonephritis with renal infiltration, mycetoma, or renal abscess. The kidney seems to be particularly vulnerable to the formation of renal cortical abscesses and obstructive masses, which usually occur at the ureteropelvic junction. A neonate with persistently positive urine or blood cultures, hypertension, renal insufficiency or acute renal failure, or oliguria or anuria should undergo ultrasound imaging to determine the presence of a bezoar-associated obstructive uropathy, which requires immediate attention. Urinary catheters or nephrostomy tubes may become colonized with *Candida* and result in secondary infections that may range from asymptomatic to invasive disease with obstruction.

CNS involvement occurs in 3 to 23 percent of neonates with systemic candidiasis; percentages of 54 to 64 percent have been reported in a few series. In addition to causing meningitis, *Candida* may invade the brain tissue, through hematogenous dissemination, producing focal nodular encephalitis, with minimal inflammation of the meninges. The diagnosis of candidal meningoencephalitis requires a high index of suspicion, followed by thoughtful and careful evaluation.

Candida meningitis may occur in the absence of positive blood cultures; CSF pleocytosis may be minimal or absent, and elevated protein or hypoglycorrhachia is an inconsistent finding. Gram-stained smears of CSF rarely reveal budding yeast, even when CSF cultures are positive for *Candida*. More recent reviews determined that meningitis with *Candida* isolated from the CSF occurred in 8 percent of ELBW infants, but only 37 to 52 percent

had *Candida*-positive blood cultures. CSF findings in neonates diagnosed with *Candida* meningitis also may vary. Of neonates with *Candida* meningitis, 43 percent may have normal CSF. Fernandez and associates,[9] in a 10-year review of candidal meningitis in 23 infants in an NICU, reported that pleocytosis occurred in only 39 percent of infants and hypoglycorrhachia occurred in 25 percent, despite a positive CSF culture for *Candida* in 74 percent of infants. The remaining neonates are diagnosed when a positive blood culture occurs with an abnormal, but culture-negative, CSF. *Candida* also may colonize and infect external ventricular drains placed for management of hydrocephalus.

Ventriculitis, brain abscesses, and brain calcifications are unusual complications of *Candida* meningitis that can be diagnosed with brain imaging procedures. Mortality or neurodevelopmental disabilities in survivors may occur in 73 percent of neonates with *Candida* meningitis.

Endocarditis is estimated to occur in 5 to 15 percent of neonates with systemic candidiasis. It is a serious and potentially fatal complication of neonatal systemic candidiasis, with reported fatality rates of 25 to 73 percent. *C. albicans* has been isolated most often, followed by *C. parapsilosis*. *Candida* endocarditis may occur in neonates with normal hearts and neonates with structural heart disease and as a postoperative complication of cardiac surgery. *Candida* endocarditis in neonates may differ in presentation from *Candida* endocarditis in older children and adults. It usually occurs in premature neonates with persistent candidemia associated with an indwelling vascular catheter. Most neonates with *Candida* endocarditis have structurally normal hearts, however, and not all reported cases in neonates have been associated with vascular devices. The presentation of *Candida* endocarditis in neonates may be acute and associated with an episode of persistent candidemia, or late onset, often discovered weeks or months after a presumably silent or resolved episode of candidemia. Cardiac murmurs may be absent. Early literature reports consisted mostly of autopsy diagnoses; however, more recently, echocardiography has proved to be a valuable tool in establishing the diagnosis of *Candida* endocarditis. Intracardiac vegetations on the mitral, tricuspid, and aortic valves, or the presence of a right atrial mass, in association with persistently positive blood cultures for *Candida*, strongly supports the diagnosis of endocarditis.

Eye disease may occur in 3 to 11 percent of neonates with systemic candidiasis; figures as high as 45 percent have been reported. Candidal eye disease may complicate systemic candidiasis in term, near-term, and preterm infants. More recent reports suggest, however, that the prevalence of ophthalmologic complications in hospitalized infants and children, including premature VLBW infants who are treated aggressively and survive candidemia, may be decreasing. Eye disease may occur on the first day of systemic candidiasis but more often is associated with prolonged candidemia. Advanced eye disease may be visible on routine examination; however, establishing the diagnosis of endophthalmitis early requires indirect ophthalmoscopy by an ophthalmologist. Most lesions involve the retina and choroids; characteristic lesions include unilateral or bilateral yellow-white fluffy, retinal, or free-floating vitreal opacities or balls, often accompanied by hemorrhage or inflammatory vitreous haze. The iris and lens of the eye also may be involved. Lens abscesses manifesting as lens opacities or cataracts also may occur, and they may be a nidus of ongoing infection poorly reached by systemic antifungal therapy and a source for recurrent disease. Untreated, *Candida* endophthalmitis also may progress and produce corneal thinning and perforation of the globe. Rarely, *Candida* endophthalmitis may mimic retinoblastoma. In addition, VLBW infants who experience candidemia may have concomitant endophthalmitis and retinopathy of prematurity or they may develop more severe retinopathy of prematurity (stage 3 or beyond) or retinal detachment and require laser therapy. Premature, high-risk, VLBW infants with candidemia should be monitored closely for *Candida* eye disease and for progression of retinopathy of prematurity.

Osteoarthritis is a rare manifestation of systemic candidiasis in neonates. It may occur temporarily associated with persistent candidemia or as a late complication, weeks to months later, after apparent resolution of an episode of candidemia. In addition to premature infants, newborns with underlying inherited disorders of metabolism also may be at increased risk. Clinical features of candidal osteoarthritis in neonates are similar to the features of osteoarthritis caused by bacterial pathogens and include warmth, pain, tenderness, and swelling of the extremity and diminished range of motion. Imaging may show swelling of soft tissue and joint and cortical bone erosion. Culture of aspirated joint fluid or biopsy of bone tissue positive for *Candida* spp. confirms the diagnosis.

Intra-abdominal infections, including enteritis, necrotizing enterocolitis (NEC), and peritonitis, and intra-abdominal and hepatosplenic abscesses are estimated to occur in 8 percent of neonates with invasive systemic candidiasis. *Candida* peritonitis and sepsis may complicate surgical procedures performed on the intestine for congenital bowel atresias or bowel perforation associated with NEC. Distinct from NEC is idiopathic spontaneous focal intestinal perforation (SFIP), which occurs rarely in VLBW infants and has been associated with systemic candidiasis in half of cases. SFIP is approximately 12-fold less common than NEC in preterm neonates and has a distinct combination of clinical and laboratory features that help distinguish it from NEC. Prognosis and management differ, so it is important to understand the difference between these two clinical entities. Neonates with SFIP are more likely than neonates with NEC to be smaller at birth, have lower Apgar scores, experience early hypotension or hypothermia, and require more intensive neonatal resuscitation. Neonates with SFIP present acutely in the second or third week of life (mean, 16.7 days of life), with distention and a bluish discolored abdomen. Radiographs in SFIP reveal a gasless abdomen without pneumatosis intestinalis or portal venous gas commonly associated with NEC. SFIP frequently is an easily resectable focal area of necrosis associated with a single perforation less than 1 cm in size, often located in the terminal ileum, but also may involve the colon or stomach. The remaining

bowel may be covered with serosal exudate, but otherwise it appears normal. In contrast, NEC often involves large areas of transmural bowel necrosis that are difficult to resect completely in many patients; *Candida* and other organisms may be seen in multiple sections of resected bowel. Histologic findings in SFIP show focal hemorrhagic necrosis, often with *Candida* invading the bowel wall at the site of perforation only, and otherwise healthy bowel. *Candida* spp. and *S. epidermidis* or coagulase-negative staphylococci are the predominant pathogens isolated in SFIP, whereas Enterobacteriaceae predominate in peritonitis caused by NEC-associated perforations, with *Candida* spp. isolated in approximately 10 percent of cases of NEC. A peritoneal culture should be obtained in all neonates with intestinal perforation, regardless of cause, because results of cultures determine the most appropriate antimicrobial therapy for bacteria and *Candida* spp.

Acquired pulmonary candidiasis with pneumonia may occur in 8 to 10 percent of ventilated premature neonates and must be differentiated clinically and radiographically from asymptomatic *Candida* colonization and pneumonia caused by other pathogens.

Diagnosis

Congenital or acquired cutaneous candidiasis may be diagnosed by the presence of budding yeast organisms in scrapings of skin lesions, with the species involved established by culture. Invasive dermatitis caused by *Candida* can be differentiated from benign cutaneous dermatitis by skin biopsy. Histopathologic evidence of organisms beyond the stratum corneum is evidence of more serious invasive dermatitis that leads to potentially fatal systemic candidiasis.

Congenital or acquired systemic candidiasis in a fetus or neonate is established by isolation of *Candida* spp. in culture from a normally sterile body fluid, such as amniotic fluid, urine, blood, or CSF, or from an involved site, such as joint or bone or from abscess. The presence of characteristic yeast or fungal elements in tissue specimens from the placenta or the umbilical cord supports diagnosis of congenital candidiasis. In the evaluation of an infant for possible candidemia, blood for culture should be obtained from a peripheral vein or artery and through all intravascular catheters in place at the time. In addition, at least one blood culture should be obtained after removal of a colonized catheter to determine if candidemia persists after the catheter is removed. Infants whose urine, blood, or CSF cultures yield *Candida*, especially if persistently positive, should have further evaluation done to detect any evidence of dissemination that would influence the prognosis and duration of antifungal therapy. Culture of CSF should be performed if candidemia is documented, even if CSF indices are normal. Urine obtained by suprapubic bladder aspiration, often facilitated by ultrasound guidance, is an excellent source for recovery of *Candida*. If the urine grows *Candida*, renal or systemic infection is suggested. Bag specimens of urine are unreliable for establishing the diagnosis because of the high rate of perineal candidal colonization in infants. Catheterized urine specimens, although preferable to specimens obtained by bag, may be contaminated from contact with perineum and penis. Urine obtained from an indwelling urinary catheter may represent colonization of the catheter; a repeat specimen obtained using sterile technique, at least 24 hours after removal of the catheter, is recommended. Fungal culture of urine may yield candidal growth in a premature neonate with disseminated candidiasis, even when other body fluids, such as blood and CSF, do not. Microscopic analysis of urine, Gram-stained smear of urine, or potassium hydroxide preparation of freshly obtained urine may show evidence of yeast or fungi, providing evidence for a presumptive diagnosis and early initiation of antifungal therapy. In addition to cultures of blood, CSF, and urine, cultures of all clinically involved sites, such as joints, bones, and abscesses, should be performed. Respiratory cultures for *Candida* are associated with pneumonia, and invasive pulmonary candidiasis may be present. Routine laboratory evaluations may support the diagnosis of systemic or invasive candidiasis. Persistent thrombocytopenia is a frequent early finding in infants with systemic candidiasis. Additional laboratory tests, such as a complete blood cell count, liver function tests, and determination of serum glucose, blood urea nitrogen, and creatinine, may be helpful in assessing the degree of systemic involvement.

Treatment

Oral candidiasis or thrush in an otherwise healthy infant is treated with oral nystatin suspension or gentian violet. Superficial cutaneous candidiasis in an otherwise healthy neonate is treated with topical nystatin cream or powder. When the diaper area is extensively involved, oral nystatin therapy may be administered as well in an attempt to eliminate the yeast from the gastrointestinal tract. Cutaneous candidiasis that persists or evolves into invasive candidiasis requires systemic antifungal therapy, usually with amphotericin B or fluconazole.

Congenital candidiasis usually requires only topical antifungal therapy in an otherwise healthy newborn; neonates who have pulmonary involvement or who are preterm should receive systemic antifungal therapy because they are at greater risk for dissemination and a poor outcome. In these instances, amphotericin B or fluconazole may be used for approximately 10 to 25 days, until clinical signs and symptoms have resolved.

Prompt systemic antifungal therapy, usually with amphotericin B or fluconazole, is indicated if even a single blood culture from a neonate is positive for *Candida* spp. In addition to removal of the catheter, systemic antifungal therapy should be administered for at least 10 to 14 days. If the peripheral blood culture also is positive for *Candida* spp., or end-organ disease is present, dissemination via the bloodstream may have occurred, and most experts recommend duration of antifungal therapy to be at least 25 to 30 days.

Isolation of *Candida* spp. from urine obtained from an indwelling catheter suggests possible colonization of the catheter, requiring removal of the catheter if the infection is to be eradicated. Isolation of *Candida* spp. from a urine specimen obtained by sterile technique denotes invasive

renal or systemic disease and requires further evaluation and systemic antifungal therapy. In some patients, medical therapy alone may eradicate the *Candida* infection, even if partial obstruction is present. Some neonates may require an urgent surgical or endoscopic procedure, however, to relieve the obstruction and restore renal function. Duration of antifungal therapy required for cure may range from 25 to 42 days or longer and should be guided by microbiologic cure and resolution of lesions by imaging studies.

Treatment of meningoencephalitis caused by *Candida* spp. in a neonate usually requires systemic therapy for at least 30 days; longer courses of treatment may be required if ventriculitis or brain abscesses or nodules are present. Repeat CSF examination and culture before discontinuing antifungal therapy is recommended to document sterilization and improved CSF parameters of white cells, glucose, and protein. If *Candida* ventriculitis is associated with an indwelling ventricular drain or shunt, prompt removal of the device also is indicated. Repeat CSF examination and culture should be done every 24 to 48 hours until sterile, and treatment should be continued when, and for at least a week after, the drain or shunt is replaced.

Treatment of endocarditis or septic thrombophlebitis caused by *Candida* spp. requires prolonged antifungal treatment, at least 30 days and usually 42 to 60 days, depending on clearance of candidemia, clinical progress, and resolution of intracardiac vegetations or lesions as documented by echocardiography. Consultation with a cardiologist or cardiovascular surgeon is recommended. If septic thrombophlebitis with vascular abscess is present, or an enlarging valvular mass obstructs blood flow, surgical intervention may be considered. Reports of resolution of endocarditis with medical therapy alone suggest, however, that it may be a valid option to consider, especially for neonates who are hemodynamically stable, with right-sided, nonvalvular lesions.

Treatment of eye disease, such as endophthalmitis, requires systemic antifungal therapy for 25 to 42 days, and consultation with an ophthalmologist is recommended to assess the extent of disease, presence or progression of comorbid retinopathy of prematurity, and response to therapy. If an abscess of the lens is present, surgical drainage or lensectomy may be necessary. Long-term follow-up of neonates with *Candida* endophthalmitis suggests that early medical therapy results in cure for most neonates who survive systemic candidiasis and that invasive procedures usually performed in adults with *Candida* eye disease, such as vitreous taps or intravitreal injections of medications, are unnecessary in most neonates. Neonates with invasive candidiasis should be observed closely, however, for progression of retinopathy of prematurity. Renal disease caused by invasive *Candida* spp. usually responds to systemic antifungal therapy, the duration of which usually is at least 25 days. Longer duration of therapy may be required to eradicate renal mycetomas, abscesses, or masses ("fungal balls"). If obstructive uropathy is present, urologic consultation is recommended to determine if nephrostomy or other diverting procedure is indicated to relieve the obstruction temporarily.

Treatment of osteoarthritis caused by *Candida* spp. usually requires prolonged duration of systemic antifungal therapy (≥42 days). Aspiration or surgical drainage by an orthopedic surgeon may be necessary if there is an infected joint or bone abscess.

Peritonitis associated with NEC or SFIP usually requires at least 25 days of systemic antifungal therapy, but longer duration may be required if intra-abdominal abscesses develop. Surgical management of SFIP also differs from that of NEC; simple surgical procedures, such as suturing or resection with primary anastomosis, may be all that is required for treatment of SFIP, whereas NEC may require extensive bowel resection.

Duration of systemic antifungal treatment for pulmonary candidiasis is not well established. Treatment should be guided by clinical and radiographic improvement; however, 25 days is likely to be adequate for most patients.

Prevention

The high frequency and significant morbidity and mortality rates associated with *Candida* infections in VLBW neonates have been the impetus behind animal models and clinical studies of preventive strategies using antifungal agents. Single-center and cohort studies and a large, multicenter, randomized, double-blind, placebo-controlled trial have shown that fluconazole prophylaxis (administered daily, every other day, or twice weekly either orally or intravenously for 4 to 6 weeks after delivery) reduces *Candida* colonization, invasive candidiasis, or mortality rates in high-risk, VLBW premature neonates weighing less than 1500 g.[6] Emergence of fluconazole resistant *Candida* spp., including *C. krusei* and *C. parapsilosis*, may occur. Also disease caused by invasive yeasts other than *Candida* spp. may occur. An outbreak of *Rhodotorula mucilaginosa*, a fluconazole-resistant yeast, occurred more recently in an NICU that routinely administered prophylactic fluconazole.

Invasive Yeasts Other Than Candida

Congenital and perinatal infections with the encapsulated yeast *Cryptococcus neoformans* have been reported. Fetal demise may occur, especially in pregnant women with untreated or severe disease. Neonates also may aspirate the organism during delivery and have fever and respiratory symptoms; meningitis, gastrointestinal involvement, and disseminated disease also may occur. Neonates and young infants with disseminated *C. neoformans* also may have a congenital immune disorder, such as severe combined immunodeficiency. Systemic antifungal treatment with amphotericin B is preferred, used in combination with 5-fluorocytosine (5-FC). Although *C. neoformans* seems to be susceptible to triazole agents, experience using these compounds to treat neonates with cryptococcosis is limited.

The *Malassezia* genus of yeasts includes seven species. The six lipophilic species are *Malassezia furfur*, *Malassezia globosa*, *Malassezia obtusa*, *Malassezia restricta*, *Malassezia*

slooffiae, and *Malassezia sympodialis*, and one species, *Malassezia pachydermatis*, is not strictly lipophilic. *Malassezia* spp. frequently colonize the skin of neonates. By the time they are 1 week old, 5 percent of neonates have positive skin cultures for *Malassezia* spp.; by 2 weeks of age, 37 to 51 percent of VLBW premature neonates have positive skin cultures. By the time they reach 3 to 6 months of age, healthy newborns have been observed to have colonization rates of 48 to 91 percent, as have preterm neonates in the NICU. *Malassezia* spp. can be introduced into the NICU on the hands of health care workers and transmitted to neonates; it also seems to persist on environmental surfaces such as incubators. The species most frequently associated with neonatal infections and NICU outbreaks include *M. furfur*, *M. pachydermatis*, *M. sympodialis*, and *M. globosa*. Skin infections with *M. furfur* and *M. sympodialis* in neonates have been associated with nonfollicular pustulosis skin conditions, such as neonatal cephalic pustulosis and neonatal acne. Skin scrapings of the pustules may show neutrophilic cells and fungal or yeast organisms when examined under the microscope, and fungal culture confirms the organism. Neonatal cephalic pustulosis usually is a benign, self-limited condition of the skin and responds to topical antifungal therapy. It must be differentiated, however, from more invasive forms of yeast and fungal diseases. Skin infections with *M. globosa* and, to a lesser extent, *M. sympodialis* are associated with pityriasis versicolor. Intravascular catheters may become colonized with *M. furfur* or *M. pachydermatis* and cause bloodstream infections, often with serious complications in VLBW preterm neonates. Risks for development of invasive disease include previous treatment with broad-spectrum antibiotics and prolonged use of intravascular catheters and intravenous fat emulsions or lipid infusions. Neonates may have systemic signs of sepsis, pulmonary decompensation, and thrombocytopenia. Complications of catheter-associated bloodstream infections with *M. furfur* include peripheral thrombophlebitis, thromboembolism, catheter occlusion, adhesion of the vascular catheter to the vein wall, and endocarditis with intracardiac mass and thromboembolic phenomena. Neonatal meningitis and urinary tract infections associated with *M. furfur* and *M. pachydermatis* also have been reported. Cultures of blood, catheter tip, urine, CSF, and involved tissue should be obtained. The organism also has been seen on peripheral blood smear. Diagnosis may be elusive, however, because recovery of *Malassezia* spp. in routine cultures is rare; if the diagnosis is suspected, special fungal cultures on Sabouraud dextrose agar overlaid with sterile olive oil or media containing long-chain fatty acids may enhance recovery of lipophilic *Malassezia* spp.

Pichia (formerly *Hansenula*) *anomala* and *Pichia ohmeri* are emerging yeasts that may cause infection in preterm VLBW neonates and infants with severe combined immunodeficiency. In some NICUs, 17 percent of preterm neonates may be colonized, and single cases and NICU outbreaks associated with indwelling catheters, administration of total parenteral nutrition solutions, and abdominal surgery have been described. Invasive diseases in preterm neonates include bloodstream infections, sepsis syndrome, abscesses, and meningitis with ventriculitis. Management includes removal of indwelling catheters and systemic antifungal therapy.

Trichosporon spp. colonize the hair, skin, mucous membranes, and gastrointestinal tract. *Trichosporon beigelii* has caused invasive dermatitis, late-onset sepsis, pulmonary infiltrates, and urinary tract infections in VLBW preterm neonates with intravascular catheters. It also may cause endophthalmitis and endocarditis. *Trichosporon asahii* infection in neonates has been reported more recently, suggesting that this species has emerged as a neonatal pathogen. *Trichosporon* spp. have been isolated from blood, urine, tracheal aspirates, skin lesions, and catheter tip cultures from neonates. The organism may be identified preliminarily as a germ-tube negative yeast and be confused initially with *Candida* spp. Breakthrough *Trichosporon* infections in patients receiving antifungal agents for candidemia have been reported. The clinician may erroneously attribute persistently positive cultures to a resistant *Candida* spp. rather than *Trichosporon* spp. *Trichosporon* spp. also share heat-stable antigens with *C. neoformans* and produce false-positive cryptococcal antigen tests. A real-time PCR assay to detect *T. asahii* DNA in sera has been developed and may help facilitate rapid establishment of the diagnosis of this potentially fatal infection. The organism has unpredictable susceptibility to antifungal agents, and there are no standardized recommendations for management of neonates with invasive *Trichosporon* infection. Most neonates have been treated with amphotericin B deoxycholate or liposomal amphotericin B combined with voriconazole.

Rhodotorula spp. are another emerging opportunistic yeast that has caused catheter-associated bloodstream infections in neonates.

Invasive Fungal Diseases

Congenital and Perinatal Transmission

Fetal demise, congenital infection, and perinatal transmission associated with the endemic dimorphic fungi *Coccidioides immitis* and *Blastomyces dermatiditis* have been described. Published case reports are very rare, however. Third-trimester acute infection with *C. immitis* seems to carry increased risk for developing severe illness for the mother and fetus. Perinatal transmission for both organisms likely occurs from neonatal aspiration of infected cervicovaginal secretions from a chronically infected maternal genitourinary tract. Cultures of urine, respiratory secretions, and lung tissue are most likely to yield the organisms. If coccidioidomycosis or blastomycosis is diagnosed in a neonate, treatment with systemic amphotericin B is recommended.

Acquired Invasive Fungal Disease

Invasive fungal disease acquired by VLBW or ELBW premature neonates involves primarily the skin, lungs, or gastrointestinal tract. Because many of the invasive fungi that affect neonates also are angioinvasive, sepsis syndrome with hematogenous dissemination to lung, liver, spleen, CNS, and eye may occur rapidly.

Aspergillus. Aspergillus spp. include *Aspergillus flavus*, *Aspergillus fumigatus*, *Aspergillus glaucus*, *Aspergillus nidulans*, *Aspergillus niger*, and *Aspergillus terreus*. *Aspergillus* spp. frequently are found in the environment and the hospital. Infection in neonates and outbreaks in NICUs have been associated with nearby construction or renovation. Diseases associated with *Aspergillus* infection of the neonate include primary cutaneous aspergillosis or invasive dermatitis, pulmonary aspergillosis, and disseminated aspergillosis. Disseminated disease may involve the heart, liver, spleen, lungs, CNS, or eye.

Neonatal aspergillosis usually manifests in the second week of life. Risk factors include extreme prematurity and VLBW or ELBW, administration of steroids and broad-spectrum antibiotics, hyperglycemia, and trauma of the extremely vulnerable skin of the premature infant. The delicate skin of VLBW infants can be macerated easily by adhesive tape, traumatized at the site of insertion of an indwelling intravascular catheter or by surgical procedures, or damaged by pressure sores, providing a portal of entry for the fungus. Invasive fungal dermatitis then occurs. *Aspergillus* spp. also may gain entry through the lungs and cause invasive pulmonary aspergillosis. Because the fungus has a predilection for invasion of blood vessels, it can disseminate quickly in the bloodstream and occlude vessels, causing thrombosis, infarction, and necrosis of tissue. Establishment of the diagnosis requires a high index of suspicion and documentation of the fungus by histopathologic examination and culture of the involved tissue or organ. Suspicious skin lesions may appear early as erythematous plaques, vesicles, scales, or persistent maceration; advanced disease may show dark, necrotic skin lesions; skin biopsy that shows invasion below the stratum corneum establishes the diagnosis of invasive fungal dermatitis. *Aspergillus* also may be recovered from tracheal aspirate cultures, ascites, and CSF. No studies have evaluated the performance of galactomannan antigen tests for the early diagnosis of invasive aspergillosis in neonates.

Early diagnosis followed by prompt and aggressive treatment of a neonate with invasive aspergillosis is important to minimize the usually high morbidity and mortality rates associated with this disease. Traditional treatment has included prolonged, high-dose amphotericin B deoxycholate or lipid complex and surgical excision of accessible tissue, such as the skin and soft tissue, if local disease progresses despite administration of systemic antifungal therapy. Treatment failures frequently occur. More recently, case reports of premature neonates with primary cutaneous aspergillosis who were treated successfully with voriconazole alone or in combination with amphotericin B lipid complex and micafungin have been published.

Zygomycetes (Absidia, Rhizopus, Mucor, and Rhizomucor). Zygomycosis, a term preferred now over mucormycosis, usually is caused by the following species of fungi: *Absidia (Absidia corymbifera)*, *Rhizopus (Rhizopus arrhizus*, *Rhizopus microsporus)*, *Mucor (Mucor amphibiorum*, *Mucor circinelloides*, *Mucor hiemalis*, *Mucor indicus*, *Mucor racemosus*, *Mucor ramosissimus)*, and *Rhizomucor (Rhizomucor pusillus*, *Rhizomucor miehei*, *Rhizomucor variabilis)*. Zygomycosis in a neonate usually manifests during the second and third weeks of life. Health care–associated outbreaks have been linked to contaminated dressings, bandages, or armboards. Risk factors for acquisition of infection include VLBW; extreme prematurity; indwelling intravascular catheters; exposure to elastic bandages, adhesive dressings and tapes, and armboards or tongue depressors used to splint extremities; and host factors such as congenital immunodeficiency or genetic disorders of metabolism that cause metabolic acidosis.

The Zygomycetes are angiotrophic and aggressively invade blood vessels very early in the disease process. Invasion of blood vessels leads to thrombosis, infarction, and tissue necrosis; destruction of local tissue can be extensive, and the fungus may disseminate throughout the body and CNS. The most common presentation of invasive zygomycosis in neonates is primary cutaneous disease. Cutaneous zygomycosis usually begins at an area of minor skin trauma or at the site of intravenous catheter insertion that has come in contact with adhesive tape or bandages, first appearing as a cluster of necrotic vesicles or scales, which then rapidly progresses to extensive necrotizing cellulitis. It usually involves the skin and soft tissues of the upper extremities, but the lower extremities, abdominal wall, or face also may be presenting sites.

Gastrointestinal zygomycosis in a premature neonate often mimics NEC clinically, but without the characteristic radiographic bowel patterns; rarely, it has presented as Hirschsprung disease. Intestinal perforation, of small or large bowel or appendix, with secondary peritonitis, may occur. Rhinocerebral zygomycosis classically manifests in diabetics with ketoacidosis, but it also may affect neonates with conditions associated with metabolic acidosis and premature infants. The fungus enters via the nasal passages and invades the sinus cavities and orbits, spreading to the CNS by fungal thrombosis of cavernous sinus and internal carotid artery. Pulmonary zygomycosis also may occur, either as a primary pneumonia with consolidation and necrosis or secondary to vascular dissemination from a cutaneous or gastrointestinal source. Disseminated zygomycosis is a fatal fungal sepsis syndrome, usually involving all major organ systems and the CNS.

Diagnosis is established by histopathologic examination of tissue, in which characteristic fungal elements invading the tissue and blood vessels can be seen. Fungal culture confirms the identification of the fungus. Successful management includes early diagnosis and aggressive surgical débridement and resection of involved tissues, to clear margins of resection. Amputation or extensive skin grafts may be necessary in some patients. Aggressive surgery is important because the fungus is resistant to most currently available antifungal agents, including the echinocandins and first-generation and second-generation triazoles. The fungus may be inhibited by amphotericin B given in high doses (1.5 mg/kg/day of amphotericin B deoxycholate or ≥5 mg/kg of lipid formulations), which should be administered as soon as the diagnosis is suspected. The newest triazole compound, posaconazole, seems to have activity against zygomycetes, but experience in administering this new agent to neonates is unavailable.

Treatment

Invasive disease of the neonate caused by fungi is treated with antifungal agents. The choice of antifungal agents available to treat invasive fungal disease of the neonate include the traditional polyene antibiotics, nystatin and amphotericin B deoxycholate, and the pyrimidine analog 5-FC, as well as lipid formulations of amphotericin B, first-generation triazoles (fluconazole and itraconazole), second-generation triazoles (posaconazole, ravuconazole, and voriconazole), and echinocandins (caspofungin, micafungin, and anidulafungin). The choice of which antifungal agent to administer, and the duration of treatment, should be guided by the reported susceptibility pattern of the fungus, and dosages should be based on available pharmacokinetic information for neonates.

CONGENITAL TOXOPLASMOSIS

Congenital toxoplasmosis results from placental infection that develops after primary maternal infection with *Toxoplasma gondii* and subsequent hematogenous spread to the fetus (Table 66-4).[14]

The clinical manifestations of congenital toxoplasmosis in newborns generally are indistinguishable from the manifestations associated with other agents of congenital infection, such as CMV and *T. pallidum*. Many neonates with congenital toxoplasmosis are seemingly asymptomatic at birth. The most characteristic clinical findings, frequently referred to as the *classic triad of congenital toxoplasmosis*, are chorioretinitis, intracranial calcifications, and hydrocephalus. They are seen in approximately 86 percent (chorioretinitis), 37 percent (intracranial calcifications), and 20 percent (hydrocephalus) of symptomatic infants. These conditions often are accompanied by a combination of signs and symptoms, including anemia (59%), jaundice (43%), splenomegaly (41%), seizures (41%), fever (40%), hepatomegaly (34%), lymphadenopathy (32%), microcephaly (9%), and eosinophilia (9%).

TABLE 66-4 **Vertical Transmission and Severity of Disease for *Toxoplasma gondii* by the Timing of Maternal Infection During Pregnancy**

	Trimester of Maternal Infection		
	First	**Second**	**Third**
Overall transmission rate (%)	15	30	60
Proportion of infected children with specific disease severity			
Stillborn/perinatal death (%)	35	7	0
Subclinical (asymptomatic) (%)	18	67	90
Mild disease (%)	6	18	10
Severe disease (%)	41	8	0

The diagnosis of congenital toxoplasmosis can be established by isolating the organism from infected body fluids and tissues, such as the placenta, amniotic fluid, fetal blood obtained by cordocentesis, umbilical cord blood, infant blood, and CSF. Alternatively, a diagnosis can be established by histopathologic examination of the placenta in which tachyzoites are revealed. PCR has been used successfully to detect *Toxoplasma* DNA in amniotic fluid, placenta, CSF, and fetal and infant blood. The most practical and widely used method of establishing the diagnosis is by testing maternal and newborn blood for serologic evidence of *Toxoplasma* infection by measuring *T. gondii*–specific IgG and IgM antibodies. Consultation with a recognized reference laboratory* for toxoplasmosis testing is recommended.

Treatment with spiramycin of an acutely infected woman during pregnancy may prevent transmission of the infection to the fetus. Treatment during the first year of life with pyrimethamine, sulfadiazine, and leucovorin is effective treatment for acute disease and improves long-term outcome in congenital toxoplasmosis.[14]

Routine serologic screening of women during pregnancy has been an effective means of prevention in France and Austria, and it has been advocated in other areas where the incidence of congenital toxoplasmosis remains high. Another focus of prevention should be on educating women of child-bearing age to avoid cat feces in litter boxes and outdoor sandboxes and gardens and avoid ingestion of raw meat and mutton.

CHLAMYDIA, MYCOPLASMA, AND UREAPLASMA INFECTIONS IN THE NEONATE

C. trachomatis is a cause of neonatal conjunctivitis and perinatally acquired infant pneumonia. The introduction of systematic screening and treatment of pregnant women has resulted in a dramatic decrease in the number of perinatal chlamydial infections in developed countries. However, in countries in which pregnant women are not screened routinely, including many developing countries, *C. trachomatis* remains the most frequent cause of neonatal conjunctivitis. The incubation period of *C. trachomatis* conjunctivitis is 5 to 14 days after delivery—or earlier if premature rupture of membranes has occurred. The manifestation is extremely variable and ranges from mild conjunctivitis with scant mucoid discharge to severe bilateral conjunctivitis with copious purulent discharge, chemosis, friable mucosa, and pseudomembrane formation. Eyelid erythema and edema frequently are present. A Gram-stained conjunctival smear initially may reveal a predominance of polymorphonuclear leukocytes. Chlamydial conjunctivitis needs to be differentiated from gonococcal ophthalmia or other bacterial and viral causes of conjunctivitis in the neonate. Infants with pneumonia will have symptoms appear between the ages of 2 weeks and 12 weeks of age, with cough, congestion, tachypnea,

*Toxoplasmosis Serology Laboratory, Palo Alto Medical Foundation, 860 Bryant Street, Palo Alto, CA 94301; 415-326-8120.

and rales. They may have eosinophilia and elevated immunoglobulins. *Chlamydia* pneumonia should be differentiated from pneumonia in neonates and young infants caused by other perinatally acquired viral, bacterial, and mycoplasma organisms. Laboratory diagnosis with detection of the organism through culture, direct fluorescent antibody antigen detection, or molecular PCR methods will establish the diagnosis. Treatment with macrolide antibiotic (i.e., erythromycin, clarithromycin, or azithromycin) is recommended. Vertical transmission of *Ureaplasma* spp. and *M. hominis* from a colonized mother to her newborn occurs in utero or during delivery.

M. hominis, *U. urealyticum*, and *Ureaplasma parvum* are the genital mycoplasmas with clinical significance in neonatal disease. Vertical transmission of *Ureaplasma* spp. and *M. hominis* from a colonized mother to her newborn may occur in utero or during delivery. Isolation of *Ureaplasma* spp. from endotracheal secretions, the nasopharynx, the throat, or gastric aspirates (or any combination of these sites) has been associated with acute pneumonia and chronic lung disease of prematurity. *M. hominis* and *Ureaplasma* spp. have been recovered from the lungs, brain, heart, and viscera of aborted fetuses and stillborn infants, with histologic findings of bronchopneumonia present in the lungs. The roles of *Ureaplasma* spp. and *M. hominis* in neonatal disease continue to be investigated and defined.

INFECTIONS OF THE COMPROMISED HOST

CHAPTER 67

Primary Immunodeficiencies

Javier Chinen • Mark W. Kline • William T. Shearer

Primary immunodeficiencies can be defined as congenital and hereditary disorders caused by an intrinsic molecular defect affecting the development or function of the immune system; and, as a consequence, patients with these conditions have increased susceptibility to infections, neoplasia, and autoimmunity. More than 165 primary immunodeficiency syndromes have been described, and the gene defects responsible for the immunologic phenotype have been identified in most of them.[2] Previously considered to be uncommon, primary immunodeficiency disorders are estimated to occur with a minimum incidence of 1 in 10,000 live births. A survey in the United States done in 2007 using a sample of 10,000 households reported a prevalence of 1 in 1,200 people with a diagnosis of primary immunodeficiency,[14] suggesting that these conditions are more common than reported in the literature.

In contrast to primary immunodeficiencies, secondary immunodeficiencies are acquired disorders, with immune dysfunction occurring as a result of exogenous factors or along with some other nonimmune primary disease processes. They are far more commonly encountered than primary immunodeficiencies. Causes of secondary immunodeficiency include infection (e.g., human immunodeficiency virus [HIV]), drugs (e.g., corticosteroids), malnutrition, and neoplastic or metabolic diseases (e.g., Hodgkin disease, diabetes mellitus). These factors may also affect the fetus while developing in utero and present in the neonatal period and should be considered in the differential diagnosis of immunodeficiencies at this age.

An immunologic evaluation is indicated when children develop unusually frequent or severe infections and when infections are caused by uncommon organisms (Table 67-1). Most of these patients are immunocompetent and may have risk factors for increased frequency of infections, such as allergic disorders, anatomic abnormalities, or other clinical conditions that secondarily produce increased susceptibility to infections, as just discussed. However, some of the evaluated children will indeed have a known primary immunodeficiency and will benefit from early diagnosis and management.

The focus of this chapter is on the elements of the medical history and physical examination that are helpful for the diagnosis of a primary immunodeficiency. Screening laboratory tests that assess clinically significant immune dysfunction are described. The most representative antibody, cellular immunity, complement, and phagocyte deficiencies are discussed. Also, a few rare, but distinctive conditions are reviewed, such as ataxia-telangiectasia and leukocyte adhesion deficiency (LAD).

INITIAL EVALUATION FOR SUSPECTED IMMUNODEFICIENCY

Medical History

A comprehensive medical history is essential in identifying children with a defective immune response. Children with immunodeficiency often have a history of frequent and severe infections (e.g., pneumonia, meningitis, septicemia, osteomyelitis, abscesses of soft tissue or an internal organ). Although infections might occur commonly throughout childhood, epidemiologic studies have established a range for the average number of infections that a normal child may suffer per year. For example, otherwise healthy children younger than 5 years of age average between three and eight episodes of upper respiratory tract infections annually.[32,39,40] By 1 year of age, 62 percent of children have had at least one episode of acute otitis media and 17 percent have had three or more episodes.[81] By 3 years of age, more than 80 percent of children have had at least one episode of acute otitis media and 46 percent have had three or more episodes. The incidence of gastroenteritis among children in the United States is approximately two to three episodes per child-year, with rates as high as five episodes per child-year among children attending daycare centers.[10,33] Occurrence of these infections during infancy or early childhood in normal children is modified by several potential factors, including immunologic immaturity or naïveté (lack of prior exposure to infectious agents), poor hygiene, mouthing behavior, allergic disease, exposure to tobacco smoking, and frequent exposure to ill contacts in the home, school, or daycare settings.

Pediatricians might also suspect immunodeficiency when the course of an infection in a child is unusually prolonged or associated with unexpected complications (e.g., lung abscess in a child with pneumonia or skull bone osteomyelitis as a complication of sinusitis). In general, infections over time at multiple body sites are more suggestive of a defective immune response than infections occurring at only one site (e.g., recurrent otitis media). In the latter circumstance, a mechanical or anatomic explanation for the infections (e.g., foreign body or occult tracheoesophageal fistula in the child with recurrent pneumonia, allergic inflammation, congenital fistulous tract to the middle ear in the child with recurrent bacterial meningitis) should be considered first.

The nature of the infection could suggest a defect in a particular compartment of the immune system. Children with primary antibody deficiencies typically experience

TABLE 67-1 When to Suspect an Immunodeficiency Disorder

- Frequency of infectious illnesses higher than expected
- Unusual severity or duration of infectious disease
- Poor response to conventional antibiotic therapy
- Unusual organisms (opportunistic infections) causing disease
- Failure to thrive, secondary to frequent illnesses
- Poor wound healing
- "Cold" *Staphylococcus* spp. skin infection (absence of pus)
- Recurrent periodontitis
- Low granulocyte or lymphocyte count

TABLE 67-2 Common Pathogens in Children with Primary Immunodeficiency

Immunodeficiency	Common Pathogens
Antibody deficiencies	*Streptococcus pneumoniae, Haemophilus influenzae, Staphylococcus aureus, Pseudomonas aeruginosa, Mycoplasma, Salmonella, Shigella, Campylobacter,* rotavirus, enteroviruses, *Giardia*
Cellular and combined immunodeficiencies	*Mycobacteria, S. pneumoniae, P. aeruginosa, Candida, Pneumocystis jiroveci,* herpesviruses, adenoviruses
Complement deficiencies	*S. pneumoniae, H. influenzae, Neisseria*
Phagocyte deficiencies	*S. aureus, Nocardia* spp., *P. aeruginosa, Serratia,* enteric gram-negative bacilli, *Candida, Aspergillus*

TABLE 67-3 X-linked Primary Immunodeficiency Disorders

- X-linked agammaglobulinemia (Bruton disease)
- Immunodeficiency with hyper-IgM (CD40 ligand deficiency)
- X-linked ectodermal dysplasia with immunodeficiency (NEMO defect)
- Immunodeficiency, polyendocrinopathy, enteropathy, X-linked (IPEX)
- X-linked lymphoproliferative syndrome
- Severe combined immunodeficiency (common γ-chain deficiency)
- Properdin deficiency
- Wiskott-Aldrich syndrome
- X-linked chronic granulomatous disease

infections caused by extracellular bacteria with polysaccharide capsules (e.g., *Streptococcus pneumoniae*, *Haemophilus influenzae* type b). In contrast, children with primary cellular immunodeficiencies often have infections with unusual or opportunistic viruses, fungi, protozoa, and mycobacteria (Table 67-2). Because of the impairment of T cell–dependent antibody responses, infections with common bacteria also may be observed. Children with primary deficiencies of complement components might have recurrent neisserial infections, and those with phagocyte deficiencies may have invasive infections with a variety of catalase-positive bacterial (e.g., *Staphylococcus aureus*, *Pseudomonas aeruginosa*, *Serratia marcescens*) and fungal (e.g., *Candida* spp., *Aspergillus* spp.) organisms. Severe or repeated infections with atypical mycobacteria suggest a defect in interleukin (IL)-12–mediated or interferon (IFN)-γ–mediated responses.

In addition to the microbial cause of infections, other clues from the clinical history may help to define the risk for and possible nature of a primary immunodeficiency. Because young infants are afforded some protection against infections by the presence of maternal immunoglobulin (Ig) G, children with primary antibody deficiencies generally have a variable onset of infections occurring between 3 and 18 months of age. In contrast, children with severe T-cell, complement, or phagocyte deficiencies may have onset of infections in the first days or weeks of life.

Omphalitis, resulting in delayed detachment of the umbilical cord stump, and poor wound healing suggest phagocyte deficiency. Hypocalcemic seizures in the neonatal period and congenital heart disease are clues for the diagnosis of DiGeorge syndrome. Severe disease caused by administration of live vaccines (e.g., bacille Calmette-Guérin [BCG] lymphadenitis, measles, poliomyelitis, varicella) justifies screening for immune response defects.

Exploring family history can further support the suspicion of a primary immunodeficiency. A history of parental consanguinity or deaths from infection or from unexplained causes during infancy or early childhood suggests a genetic defect. Many of the immunodeficiency syndromes have X-linked inheritance patterns (Table 67-3), which explains the male-to-female ratio of 5 : 1 observed in series of children with primary immunodeficiencies.

Physical Examination

In the absence of infections, the physical examination in most children with primary immunodeficiencies provides few clues pointing to an immune defect, especially when patients are very young and have not been exposed to potential pathogens.

Short stature with wasting or failure to thrive is a relatively common feature of severe T-cell deficiencies, likely secondary to recurrent infections or other chronic conditions, such as chronic or frequent diarrhea with intestinal malabsorption. Omenn syndrome is recognized by the severe rash during the newborn period. A paucity of lymphoid tissues (e.g., tonsils, lymph nodes) suggests impaired lymphocyte development. Oral candidiasis, omphalitis, and multiple skin abscesses may indicate an underlying immune disorder. Other examples of helpful physical stigmata include the characteristic facial features (Fig. 67-1) and cardiac malformations in children with DiGeorge syndrome. Telangiectasia of the

FIGURE 67-1 ■ Typical facial appearance of a child with DiGeorge anomaly. Notice the microstomia, hypertelorism, upturned nose, and posteriorly rotated and small, low-set ears. (See companion Expert Consult website for color version.)

FIGURE 67-2 ■ Telangiectases of the bulbar conjunctivae in a child with ataxia-telangiectasia. (See companion Expert Consult website for color version.)

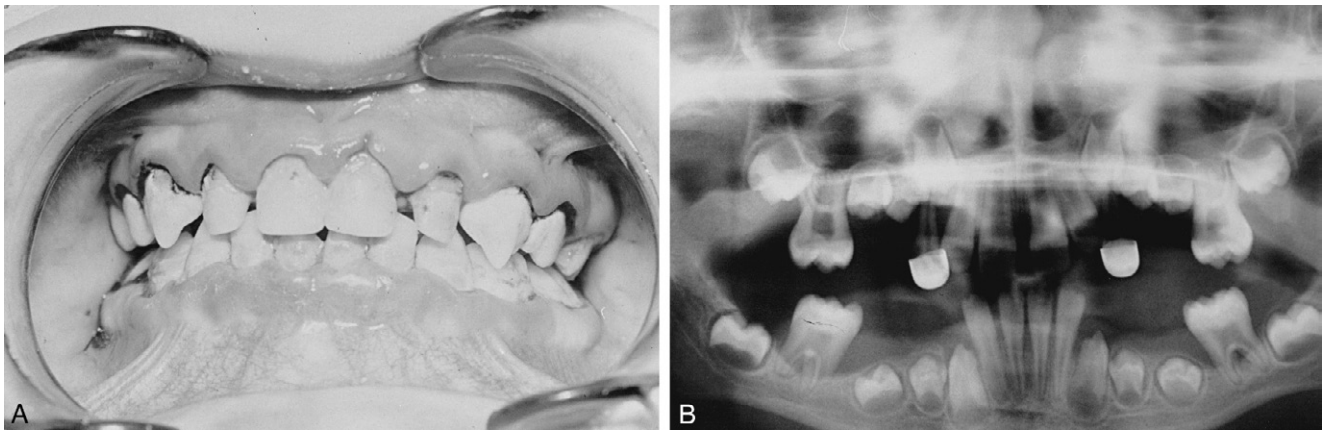

FIGURE 67-3 ■ **A,** Chronic periodontitis in a boy with leukocyte adhesion deficiency. **B,** Radiograph of the same patient shows extensive alveolar bone loss. (Courtesy Dr. Bruce Carter, Texas Children's Hospital, Houston, TX.)

bulbar conjunctivae (Fig. 67-2), nasal bridge, ears, and flexor surfaces of the extremities, with or without ataxia, suggest ataxia-telangiectasia. Chronic eczema is observed in the hyperimmunoglobulinemia E (hyper-IgE) and Wiskott-Aldrich syndromes, and severe gingivitis with secondary loss of alveolar bone and dentition can occur in children with LAD (Fig. 67-3).

Laboratory Tests

Commonly available, relatively inexpensive laboratory tests such as a complete blood cell count with differential can be used in the initial screening for immunodeficiency to exclude most severe disorders (Table 67-4). This evaluation should be targeted to the type of immunodeficiency (e.g., antibody deficiency vs. T-cell defect) suggested by the medical history and physical examination findings. Laboratory test results must be interpreted in the context of the child's age, because average normal serum immunoglobulin levels, T-cell counts, and other immune parameters physiologically change with age.[56] Because 50 to 70 percent of circulating lymphocytes are T cells, children with severe cellular (e.g., complete DiGeorge syndrome) or combined (e.g., severe combined immunodeficiency [SCID]) immunodeficiencies have absolute lymphopenia. Children with Wiskott-Aldrich syndrome typically show reduced numbers of platelets, which are small (decreased mean platelet

TABLE 67-4 **Screening Tests for Suspected Primary Immunodeficiency**

Immunodeficiency	Screening Tests
All types	Complete blood cell count (CBC)
	Peripheral blood smear, for percentage of leukocyte types
Antibody deficiency	Quantitative serum immunoglobulins: IgG, IgA, IgM
	Postimmunization specific IgG antibody titers
	Isohemagglutinins
Cellular immunodeficiency	Delayed hypersensitivity skin tests
	Chest imaging studies for thymus size
	Lymphocyte subset phenotyping
Complement deficiency	Total hemolytic complement (CH50) assay
Phagocyte deficiency	Dihydrorhodamine (DHR)-1,2,3 reduction by flow cytometry
	Neutrophil CD11a, CD11b, CD11c, CD18 expression

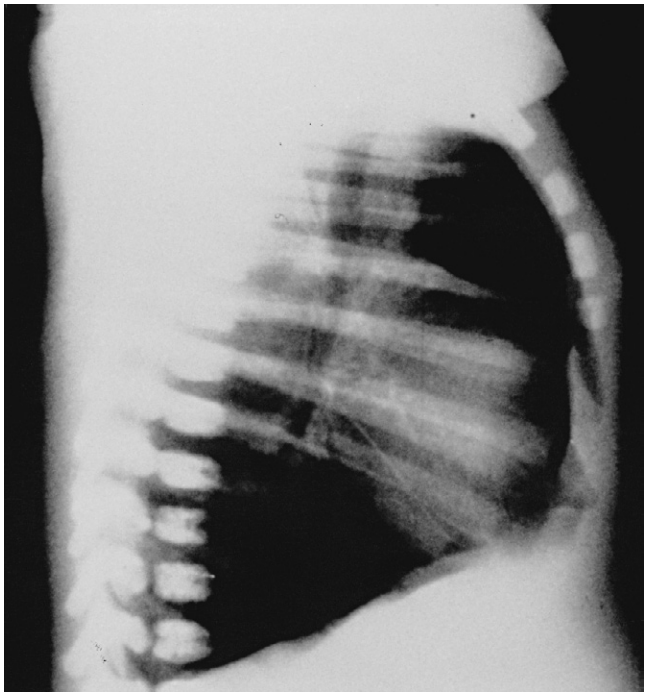

FIGURE 67-4 ■ Lateral chest radiograph of an infant with severe combined immunodeficiency. Notice absence of the normal thymic shadow.

volume), a characteristic that is specific for this syndrome and the related X-linked thrombocytopenia. Large neutrophil cytoplasmic granules, noted in blood smears, are observed in children with Chédiak-Higashi syndrome.

A complete blood cell count is also useful in excluding congenital neutropenia. Children with LAD often have the opposite, with markedly increased neutrophil and total white blood cell counts. The presence of Howell-Jolly bodies, with or without thrombocytosis, suggests anatomic or functional asplenia. Tests to rule out HIV infection, malnutrition, or metabolic disorders as causes of secondary immunodeficiency should be considered.

Evaluation of Humoral Immunity

Screening evaluation of the child with suspected antibody deficiency should include quantitative measurement of serum immunoglobulins and functional assessment of specific antibody responses. Except for the rare deficiency of antibody response to specific antigens, children with other primary antibody deficiencies have abnormalities of serum immunoglobulin concentrations. Measurement of serum IgG, IgA, and IgM concentrations identify children with panhypogammaglobulinemia and those with deficiency of a particular immunoglobulin isotype, such as selective IgA deficiency.

Functional antibody production is usually evaluated by measuring antibody titers generated in response to immunization with vaccines, such as diphtheria and tetanus toxoids. Antibody responses to polysaccharide antigens are evaluated separately using the pneumococcal polysaccharide vaccine (Pneumovax 23) after 24 months of age. Younger infants are thought to have a functional immaturity in the ability to respond to this class of antigens. Alternatively, because ABO blood group antigens are polysaccharides and cross-reacting environmental antigen epitopes are ubiquitous, antipolysaccharide antibody production can be assessed by measuring serum isohemagglutinin titers, taking into consideration that children with blood type AB do not form isohemagglutinins. The conjugated pneumococcal (Prevnar 13) and *H. influenzae* type b vaccines are not suitable for the assessment of antipolysaccharide antibody responses because they are not pure polysaccharides. Patients vaccinated with the conjugated pneumococcal vaccine can be evaluated for antipolysaccharide antibody production because the pneumococcal polysaccharide vaccine contains serotype antigens against which the conjugated vaccine does not induce protective antibodies.

Measurement of serum IgG subclasses may be indicated in children with apparent abnormalities in functional antibody production. Further evaluation of children whose screening tests indicate significant quantitative and functional antibody abnormalities should include enumeration of T- and B-cell subsets in the peripheral blood and in vitro studies of mitogen- or antigen-induced lymphocyte cell proliferation.

Evaluation of Cellular Immunity

The screening evaluation for cellular immunodeficiency starts with delayed hypersensitivity skin tests and, in the young infant, posteroanterior and lateral chest radiographs for the assessment of the size of the thymus (Fig. 67-4). If available, chest computed tomography (CT), magnetic resonance imaging (MRI), or ultrasound evaluation also may be helpful.

Delayed hypersensitivity skin tests are performed using vaccine or microbial antigens to which the child has had prior exposure. Commonly used antigens include tetanus toxoid and *Candida albicans*. Standard initial dilutions are 1:100 for both antigens, but a *C. albicans* dilution of 1:10 may be more appropriate for children 5 years of age or younger because they are less likely to have been exposed to this antigen. The diluted antigen is administered intradermally, and the skin reaction is read at 24 and 48 hours for the presence of wheal formation. Delayed hypersensitivity skin test responses depend on previous exposure to the antigen tested and often are absent in children younger than 2 years of age. Therefore, enumeration of peripheral blood T cells, T-cell subset phenotyping (i.e., $CD4^+$ or $CD8^+$ lymphocyte counts), and mitogen- and antigen-induced lymphocyte proliferation studies may be needed for a reliable assessment of cellular immune function.[56]

Evaluation of the Complement System

Deficiencies of components of the classic complement pathway can be detected by the total serum hemolytic complement (CH50) assay. This test measures the ability of proteins contained in the fresh patient serum to lyse antibody-coated sheep erythrocytes and reflects the activity of all components of the classic complement pathway from C1 through C9. Complete deficiency of any of these components results in very low levels of CH50. Mildly abnormal CH50 values might be obtained because of inadequate sample handling; single complement component levels and function testing should be pursued when the CH50 value is zero or near zero.[94] Testing of complement components C3 and C4 is available in most clinical laboratories and may be considered when complement deficiency is suspected. The alternate complement pathway is assessed with a similar assay (AH50).

Evaluation of Phagocyte Function

Few assays are available for the assessment of phagocyte function. The nitroblue tetrazolium (NBT) dye test uses the reduction of NBT to formazan by activated phagocytes to measure the oxidative metabolic responses that accompany phagocytosis. Children with chronic granulomatous disease (CGD) show reduced dye reduction (<10% of cells are formazan positive); carriers of X-linked CGD typically have between 20 and 90 percent formazan-positive cells. The specificity and sensitivity of this test largely depend on the expertise of the performing laboratory. Flow cytometry that detects hydrogen peroxide production in phagocytes using dihydrorhodamine-1,2,3 (DHR) as the fluorescent indicator has proven to be more reliable and sensitive than the NBT test.[56] More sophisticated tests available in research laboratories include assays of chemotaxis, phagocytosis, and bactericidal activity, which may be performed when the NBT or DHR test results are normal and a high clinical suspicion of a phagocyte disorder exists. Enumeration of CD11a, CD11b, CD11c, and CD18 white blood cells is indicated when diagnosis of LAD is suspected.

TABLE 67-5 **Examples of Gene Defects in Primary Immunodeficiencies**

Immunodeficiency	Gene Defect	Chromosome
Antibody Deficiency		
Agammaglobulinemia	Heavy-chain immunoglobulin	14q23
	Bruton tyrosine kinase	Xq22
Hyper-IgM syndrome	Activation-induced deaminase	12p13
	CD40 ligand *(CD40LG)*	Xq26
Cellular Immunodeficiency		
DiGeorge syndrome	Unknown, *TBX1*?	22q11.2, 10p13
Severe combined immunodeficiency	*RAG1, RAG2*	11p13
	JAK3	19p13.1
	Adenosine deaminase	20q13.11
	Common γ chain	Xq13.1
	IL-7 receptor	5p13
Ataxia-telangiectasia	ATM, DNA kinase	11q22.3
Wiskott-Aldrich syndrome	*WAS,* cytoskeleton protein	Xp11.23
Phagocyte Deficiency		
Chronic granulomatous disease	gp67phox	1q25
	gp47phox	7q11.23
	gp22phox	16q24
	gp91phox	Xp21.1
Leukocyte adhesion deficiency type I	*ITGB2*	21q22

Genetic Testing

More than 165 gene defects responsible for immunodeficiency disorders have been identified (Table 67-5). Currently, gene sequence testing for these conditions is available only in a few specialized laboratories but should be pursued when a primary immunodeficiency with a known genetic defect is suspected. Genetic studies for immunodeficiencies are used most often to confirm the diagnosis of DiGeorge syndrome, in which a microdeletion in chromosome 22 is identified by fluorescent in situ hybridization (FISH) in approximately 95 percent of patients affected.[80] Genetic testing is recommended for affected patients who are ill with infections and have abnormal immune function, for prenatal diagnosis of the unborn child with a sibling affected with a primary immunodeficiency, and for an individual who may have inherited or is a carrier of a known immunodeficiency gene defect. For some of the conditions, knowing the specific gene defect may help assessing prognosis and therapeutic options. For example, it has been reported that bone marrow transplantation for X-linked SCID (*IL2RG* gene defect) is more successful than for other forms of SCID.[17] Knowledge of the specific gene defect is also useful for genetic counseling, most often to answer the concern of parents regarding the probability of having another child with a similar condition.

Neonatal Screening for T-Cell Deficiencies

In June 2010, the U.S. Department of Health and Human Services approved the addition of SCID to the list of diseases recommended for universal neonatal screening.[77] The technique was pioneered in Wisconsin and gradually implemented in several U.S. states, including Massachusetts, California, New York, Colorado, Connecticut, Delaware, Michigan, Mississippi, and Texas, and the territory of Puerto Rico. Children with severe T-cell deficiencies, such as SCID, are born with absence of T-cell receptor excision circles (TRECs, DNA recombination by-products), which can be tested in blood spots from Guthrie cards. This program has been successful to diagnose children with severe immunodeficiency before devastating infections occur, with significant improvement of treatment outcomes.[63] It has also allowed for the estimation of the actual incidence of severe T-cell defects in different states; for example, this estimate approaches 1 in 25,000 live births in California. A similar approach for the diagnosis of B-cell deficiencies in the newborn is being developed.[12]

Management

The immunodeficient patient requires specialized care according to the specific diagnosis and patient condition. For example, hematopoietic cell transplantation is indicated for the most severe immunodeficiencies and needs careful individualized assessment of risks and benefits to provide a treatment protocol that ensures the highest survival chance.[17]

One common therapeutic measure is administration of intravenous or subcutaneous immunoglobulins (IVIG or SCIG, respectively) for patients with deficiency of IgG responses, both when presenting alone or in combination with cellular immunity defects. Other recommendations specific to patients with immunodeficiency include the avoidance of contact with infectious illness and avoidance of live vaccines[6]; the use of irradiated, leukocyte-depleted, cytomegalovirus-negative blood products when needed; antibiotic prophylaxis; and the prompt diagnosis and treatment of infections. Except for patients with severe T-cell deficiency waiting for hematopoietic cell transplants, isolation in sterile environments is not recommended because the risk for infection needs to be balanced with the severe impact in psychosocial development induced by isolation. The infection risk is also moderated with advances in the treatment and prevention of community-acquired infections (Table 67-6).

TABLE 67-6 Key Concepts in the Management of Primary Immunodeficiencies

1. *Immune function.* T- and B-cell number and function should be assessed periodically.
2. *IgG replacement therapy:* for patients with low IgG levels and poor antibody function.
3. *Immunizations.* Live vaccines should not be administered to immunodeficient patients, except to those with complement deficiency and selective IgA deficiency. Patients with complement deficiency may benefit from receiving the pneumococcal and meningococcal vaccines because of their increased susceptibility to encapsulated organisms. Household contacts of children with immunodeficiency should not receive oral poliovirus vaccines because of the risk for transmission to the immunodeficient child. Other live vaccines (BCG, MMRV) may be administered to the household contact. If the vaccine recipient develops a rash, contact with the immunodeficient child should be avoided.[7]
4. *Blood products.* When needed, patients with immunodeficiencies should receive only irradiated, cytomegalovirus-negative, leukocyte-depleted blood products.
5. *Antibiotic prophylaxis.* T cell–deficient patients should take antibiotic prophylaxis for *Pneumocystis jiroveci.* Antibiotic prophylaxis is recommended for dental and surgical procedures and should be considered for patients with recurrent infections.
6. *Infectious diseases.* Infections should be recognized promptly, and unusual pathogens should be considered. Antibiotic therapy should be started early and discontinued cautiously.
7. *Diet and activity.* Patients with immunodeficiency should have a regular diet and lifestyle but should be instructed to avoid eating raw food and playing in environments potentially highly contaminated with pathogens, including daycare centers. Strict hand washing precautions and reverse isolation may be indicated for patients with poor T-cell function.

SELECTED PRIMARY ANTIBODY DEFICIENCIES

X-Linked Agammaglobulinemia

Clinical Features

Boys with X-linked agammaglobulinemia (XLA, Bruton disease) often are healthy during the first months of life because of the protective presence of transplacentally acquired maternal IgG. As maternal immunoglobulin disappears from the infant, chronic or recurrent infections develop.[21,22,62,95] Frequent otitis media, sinusitis, pneumonia, and diarrhea are the most common findings, but infections are not limited to mucosal surfaces and bacteremia, meningitis, and osteomyelitis also may occur. The mean age at diagnosis in a retrospective study of 201 patients with XLA was 2.5 years in patients with a family history of the disease and 3.5 years when patients did not have family history.[95] *S. pneumoniae*, *H. influenzae* type b, *S. aureus*, and *P. aeruginosa* are the most common bacterial pathogens observed in the setting of XLA. *Mycoplasma* spp. infections also occur with increased frequency and have been implicated as a cause of a subacute, destructive arthritis. Gastrointestinal infections may be caused by *Salmonella*, *Shigella*, *Campylobacter*, or rotavirus. Chronic giardiasis with intestinal malabsorption has been reported with increased frequency.

Pathogenesis

The defective gene *(BTK)* maps to the midportion of the long arm of the X chromosome. The gene encodes a

cytoplasmic protein-tyrosine kinase, a signal transducer that is necessary for expansion of B-cell populations during their maturation.[85] As a consequence, blood, lymph nodes, and bone marrow contain markedly diminished numbers of B cells and plasma cells, resulting in hypogammaglobulinemia.

Diagnosis

Because of the presence of transplacentally acquired maternal IgG, the determination of serum immunoglobulin for diagnosis of XLA in the first 6 months of life does not reflect the infant's immunoglobulin production. Infants with XLA also have low concentrations of other Ig isotypes (e.g., IgA, IgM), but defining values that clearly differentiate between infants with the disease and normal infants has been difficult. Definitive diagnosis during early infancy generally relies on immunophenotyping by flow cytometry to demonstrate absence of B cells in peripheral blood. After an infant with XLA reaches 6 months of age, serum IgG concentrations usually are less than 100 mg/dL and concentrations of other immunoglobulin isotypes are low or undetectable. Isohemagglutinins are absent, and specific antibodies are not produced in response to immunization or natural infection. Recurrent infections in male family members may suggest an X-linked condition. Definite diagnosis is obtained by finding inactivating mutations in the *BTK* gene sequence.

Treatment and Prognosis

Lifetime immunoglobulin replacement therapy is indicated for all patients with XLA.[57] It decreases the frequency of serious infections, reduces the need for hospitalization, and may help to prevent the development of chronic lung disease with progressive decrease of lung function. The dose and frequency of administration of immunoglobulins are adjusted to produce serum IgG trough concentrations of at least 500 mg/dL. For most patients, IVIG is required at a dose of 400 to 600 mg/kg every 3 or 4 weeks. Equivalent doses of SCIG might be used alternatively.

Acute infections should be promptly treated in patients with XLA. Minor middle ear, sinus, and skin infections usually respond to oral antibiotics. Pneumonia and other serious focal or systemic infections should be treated initially with intravenously administered antibiotics. Empirical antibiotic therapy is directed against common bacterial pathogens, including *S. pneumoniae*, *H. influenzae*, and *S. aureus*. If possible, etiologic diagnosis should be obtained, particularly in cases of severe or chronic infection. Because serum IgG concentrations often decrease during acute infection, the serum IgG concentration should be measured and additional doses of immunoglobulins may be indicated. Chronic pulmonary disease with bronchiectasis is an important cause of death of patients with XLA. Long-term antibiotic therapy, similar to that employed in patients with cystic fibrosis, may be helpful in individual cases.

Immunoglobulin Deficiency with Increased IgM

Clinical Features

About 70 percent of cases of immunoglobulin deficiency with increased IgM (i.e., hyper-IgM syndrome) are associated with X-linked inheritance, owing to *CD40LG* gene defects, and the rest of patients show an autosomal recessive inheritance pattern.[23,43,46,52] Patients with this disorder develop recurrent pyogenic infections during infancy as transplacentally acquired maternal IgG wanes. Respiratory tract infections and chronic diarrhea with failure to thrive are common; septicemia, meningitis, and other serious systemic infections also occur. Opportunistic infections, such as *Pneumocystis jiroveci* pneumonia, are relatively common in this syndrome when the defective protein is CD40LG.

One half of patients with hyper-IgM syndrome have neutropenia. It can be intermittent but lacks the precise periodicity of cyclic neutropenia. Aphthous ulcers occur commonly. Perirectal ulcers and abscesses have also been reported. Hyperplasia of superficial and deep lymph nodes is usually found, and intestinal nodular lymphoid hyperplasia may lead to malabsorption and protein-losing enteropathy. The incidence of lymphoreticular malignancies is increased in these patients. Autoimmune conditions, including arthritis and nephritis, have been described with increased frequency compared with other children.

Pathogenesis

Males with hyper-IgM syndrome may have mutations of a gene on the X chromosome that encodes the T-cell ligand *(CD40LG)* for the B-cell surface molecule CD40.[4,8] Several patients with normal expression of CD40LG but defects in the B cell CD40 signaling pathway also have been described.[23] Interaction of CD40 with the CD40 ligand is essential for B-cell proliferation, isotype switching, and terminal differentiation of B cells to antibody-secreting plasma cells. Mutations in the activation-induced cytidine deaminase *(AICDA)* and the uracil DNA glycosylase *(UNG)* genes are other defects found in patients with the autosomal recessive form of the hyper-IgM syndrome.[52]

Diagnosis

Patients with hyper-IgM syndrome may have a characteristic increase in serum IgM concentrations in association with low to absent concentrations of serum IgA and IgG. Serum IgM concentrations may exceed 1000 mg/dL; however, they can be within normal range. Circulating B cells expressing surface IgM are found in normal numbers, but there are only a few cells bearing surface IgA or IgG. Antibody responses to immunization often are present but consist predominantly or exclusively of IgM because isotype switching does not occur. Over half of the patients are diagnosed before 1 year of age, and 90 percent of patients are diagnosed by age 4 years. Evaluation of boys with suspected immunoglobulin deficiency

with increased IgM should include a determination of CD40LG expression in activated T cells done by flow cytometry.[8]

Treatment and Prognosis

Immunoglobulin replacement therapy and antibiotic prophylaxis are indicated.[57] CD40L-deficient patients have increased morbidity and mortality compared with patients with autosomal forms of hyper-IgM syndrome, likely secondary to the X-linked condition resulting from a T-cell defect rather than a B-cell defect. Causes of mortality without definitive treatment include infections other than those affecting the respiratory tract, sclerosing cholangitis with progressive liver disease, often secondary to *Corynebacterium parvum* infection, and malignancy.[46] Human leukocyte antigen (HLA)-identical bone marrow transplantation has been successful in this condition and should be considered early after diagnosis, before severe complications occur. Administration of recombinant CD40LG has been reported to improve immune responses in these patients.[36]

Common Variable Immunodeficiency

Clinical Features

Common variable immunodeficiency (CVID) includes a heterogeneous group of disorders with similar clinical manifestations characterized by hypogammaglobulinemia with low or normal numbers of B cells, abnormal antibody production, recurrent infections, and a propensity for autoimmune conditions. Onset can occur at any time from infancy[97] to old age, but symptoms frequently begin during the second or third decades of life.[65]

The clinical manifestations of CVID are similar to those of XLA, with recurrent infections of the respiratory tract, bacteremia, meningitis, osteomyelitis, and septic arthritis. Frequently, patients develop bronchiectasis and chronic lung disease. The most common infectious organisms are *S. pneumoniae*, *H. influenzae*, and *S. aureus*.[65] Many individuals with CVID suffer from chronic diarrhea and intestinal malabsorption that have an infectious or autoimmune basis. The inflammation induced by these conditions may result in protein-losing enteropathy and may exacerbate the underlying hypogammaglobulinemia. Organisms implicated in these gastrointestinal infections include *Giardia*, *Campylobacter*, *Salmonella*, and *Cryptosporidium*. Patients with CVID have an increased frequency of ulcerative colitis, Crohn disease, atrophic gastritis with achlorhydria, viral or autoimmune chronic active hepatitis, and cholelithiasis. Approximately 22 percent of individuals with CVID develop autoimmune conditions, which include a chronic arthritis resembling juvenile rheumatoid arthritis; scleroderma, a lupus-like syndrome; hypothyroidism; and autoimmune neutropenia, anemia, and thrombocytopenia. Malignancies, such as lymphomas and gastric carcinoma, are common findings among adults with CVID. A pseudolymphoma syndrome with lymphoid hyperplasia of the lung (i.e., lymphoid interstitial pneumonia) and intestine (i.e., nodular lymphoid hyperplasia), massive splenomegaly, and mediastinal adenopathy may be seen in patients with CVID.

Pathogenesis

The pathogenesis of CVID is attributed to several different genetic defects that result in loss of antibody secretion. Bone marrow B-cell maturation is intact, and normal or low numbers of B cells are present in peripheral blood and lymph nodes. Decreased or absent memory B cells is associated with disease severity and development of autoimmune disorders and malignancies.[3,19,68] Patients with CVID appear to have an intrinsic B-cell defect that impairs the ability of these cells to differentiate into immunoglobulin-secreting plasma cells, but a variety of T-cell functional abnormalities also have been described. They include decreased lymphocyte proliferation to mitogens and antigens and reduced expression of cytokines.

Mutations in the *TNFRSF13B*, *ICOS*, *MSH5*, *TNFRSF13C*, *CD27*, *CD81*, *MS4A1*, and *CD19* genes have been individually found linked to disease in a few families with several members affected with CVID and IgA deficiency, providing a link between these two clinical syndromes and supporting the concept of multiple causes for CVID.[41,73,89,90,93]

Diagnosis

Quantitative immunoglobulin determination generally reveals a serum IgG concentration persistently less than 250 mg/dL, or less than two standard deviations below the normal range for age, with comparable decreases in other immunoglobulin isotypes. Immunophenotyping of peripheral blood lymphocytes demonstrates the presence of mature B cells expressing surface immunoglobulins, with a subset of patients having reduced counts of switched memory B cells. Antibody responses to immunizations are subnormal or absent. Because CVID usually becomes evident in adulthood, it is important to rule out conditions that might result in hypogammaglobulinemia, such as protein-losing enteropathies and B-cell lymphomas.

Treatment and Prognosis

Treatment of patients with CVID is similar to that of patients with XLA. Immunoglobulin replacement therapy is indicated and has been shown to decrease the frequency of respiratory tract infections.[47] Antibiotic prophylaxis may be indicated as an adjunctive measure in patients who continue to have infections despite adequate serum IgG levels. Because of enteric protein loss, patients with CVID who have enteropathy may require unusually large immunoglobulin doses to maintain protective serum IgG concentrations. Chronic lung disease with bronchiectasis resulting from multiple occurrences of pneumonia is the most frequent cause of morbidity and mortality.[65] CVID patients are at higher risk for developing lymphoma, splenomegaly, and autoimmune complications.

IgA Deficiency

Clinical Features

IgA deficiency is estimated to occur with a frequency of 1 in 500 people and is considered the most common immunodeficiency, although the frequency might vary widely among different ethnicities.[26] Most individuals with IgA deficiency are clinically asymptomatic.[71,76] Some patients have frequent, noninvasive viral and bacterial infections of the respiratory tract. Chronic diarrhea occurs with increased frequency, and *Giardia* is a pathogen commonly isolated from stool samples. Infections in patients with IgA deficiency usually are less severe than those observed in patients with XLA or CVID. Individuals with more severe or chronic infections often have another associated immune deficiency, such as IgG subclass deficiency[74] or, rarely, ataxia-telangiectasia.

Patients with IgA deficiency have a higher incidence of atopy than does the general population. Autoimmune disorders, including systemic lupus erythematosus, rheumatoid arthritis, and pernicious anemia, and lymphoid and gastrointestinal malignancies are more prevalent than in the general population.

Pathogenesis

The pathogenesis of IgA deficiency has been paralleled with that of CVID. The fundamental defect in both disorders appears to be a failure of B cells to differentiate into immunoglobulin-secreting plasma cells. Rare alleles of complement genes within major histocompatibility complex III on chromosome 6 have been associated strongly with the development of selective IgA deficiency and CVID, suggesting that these two disorders may be related.[92] Some individuals with selective IgA deficiency subsequently develop CVID. Inactivating mutations in *TNFRSF13B* and *ICOS* genes have been found in families with members with either of these conditions.[19]

Diagnosis

Selective IgA deficiency is diagnosed by a quantitative serum immunoglobulin determination showing subnormal concentration or absence of circulating IgA in the presence of normal amounts of the other immunoglobulins. In interpreting test results, an important consideration is that serum IgA concentrations can be undetectable in normal infants younger than 6 to 9 months of age, possibly because of a maturational delay. This diagnosis is reliable only after the child reaches 4 years of age and the IgA deficiency is persistent.

Treatment and Prognosis

Immunoglobulin replacement is generally not recommended in the management of patients with selective IgA deficiency. Although rarely reported, IgA-deficient patients are at risk for developing IgE-mediated anaphylactic reactions if the patient is sensitized to IgA and receives blood products containing IgA.[64]

IgA-deficient patients respond adequately to vaccines unless they have concomitant IgG2 deficiency. Sinopulmonary infections in individuals with IgA deficiency often require unusually long courses of antibiotic therapy. Antibiotic prophylactic for respiratory tract infections may be recommended if infections are recurrent. Parenteral antibiotic therapy sometimes is necessary for refractory cases of sinusitis or pneumonia.

IgG Subclass Deficiency

Clinical Features

The most common IgG subclass deficiency reported is IgG2, sometimes occurring in association with deficiency of IgG4 or IgA. The second most common is IgG3 deficiency, which may occur in association with IgG1 deficiency.[1,74] Many individuals with IgG subclass deficiencies are asymptomatic; others have recurrent or chronic bacterial infections, usually of the respiratory tract. Commonly implicated pathogens include *S. pneumoniae*, *H. influenzae* type b, and other encapsulated bacteria. Children with selective IgG subclass deficiency do not usually have problems with intestinal malabsorption or autoimmunity.

Pathogenesis

The pathogenesis of IgG subclass deficiency is still not well defined. T cell immunity has been reported to be intact in patients with IgG subclass deficiencies.

Diagnosis

A diagnosis of IgG subclass deficiency is supported by finding a marked decrease from age-adjusted normal values in the serum concentrations of one or more IgG subclasses, in addition to evidence of a functional impairment in antibody responses to immunizations. The total serum IgG concentration may be normal, decreased, or even elevated as a result of a compensatory increase in production of unaffected IgG subclasses.

Children with low IgG2 subclass levels may respond poorly to polysaccharide vaccines.[1,86] Responses to protein antigens (e.g., tetanus toxoid) and protein-conjugated polysaccharide vaccines (e.g., *H. influenzae* type b conjugate vaccines) may also be abnormal. Assessment of the patient's antibody responses to vaccination with polysaccharide and protein antigens can help to establish the functional significance of an IgG subclass deficiency. Because of the age-dependent development of antipolysaccharide antibody responses, such testing is not reliable in children younger than 2 years of age.

Treatment and Prognosis

Antibiotic prophylaxis of recurrent sinopulmonary infections and early and prompt treatment of infections form the cornerstone of management for symptomatic IgG subclass deficiency. Immunoglobulin replacement therapy is reserved for patients with abnormal antibody responses and a demonstrated propensity for frequent or chronic infections.[57] Because the clinical benefit of this measure in the long term has not been demonstrated, the

effectiveness and continued need for immunoglobulins should be reassessed periodically.

Transient Hypogammaglobulinemia of Infancy

Clinical Features

Infants with transient hypogammaglobulinemia come to medical attention because of recurrent respiratory tract infections (e.g., otitis media, sinusitis) and serum immunoglobulin levels that are lower than laboratory normal ranges. Septicemia, meningitis, and other serious systemic infections are rare.[59]

Pathogenesis

Transient hypogammaglobulinemia of infancy is a developmental disorder with a delay in the physiologic maturation of immunoglobulin synthesis, resulting in prolongation of the relative hypogammaglobulinemia observed in most normal infants at 4 or 5 months of age, when most maternal immunoglobulins have cleared from the child circulation. Patients with transient hypogammaglobulinemia of infancy do not appear to have any inherent defects of B-cell maturation or function or defects of specific antibody responses.

Diagnosis

The diagnosis can be made with certainty only in retrospect. Serum immunoglobulin concentrations may remain low in children until they are up to several years of age in some cases.[59] Circulating mature B-cell numbers are normal and generate normal antibody responses to diphtheria, tetanus, and pertussis vaccines.

Treatment and Prognosis

Infants with suspected transient hypogammaglobulinemia should be followed clinically, and serial serum immunoglobulin concentration measurements should be performed. Some of these children eventually are diagnosed as having CVID, selective IgA deficiency, or another secondary immunodeficiency disorder. Because it is self-limited and specific antibody production usually is normal, immunoglobulin replacement therapy is not indicated. Antibiotic prophylaxis for respiratory tract infections is indicated in selected cases with recurrent episodes of infection.

SELECTED PRIMARY CELLULAR AND COMBINED IMMUNE DEFICIENCIES

DiGeorge Syndrome

Clinical Features

DiGeorge syndrome is a relatively common genetic disorder that includes facial, cardiac, parathyroid, and thymic abnormalities.[80] It may present early in infancy as findings unrelated to immunodeficiency. Congenital heart disease, particularly truncus arteriosus and interrupted aortic arch, is usually detected in the first few weeks of life. Neonatal hypoparathyroidism occurs in almost all infants with DiGeorge syndrome, and hypocalcemic seizures or tetany is a common presenting feature in about 30 percent of cases. Characteristic facial features include microstomia and micrognathia; hypertelorism; upturned nose; arched palate; posteriorly rotated and small, low-set ears with notched pinnae; and antimongoloid slant of the eyes (see Fig. 67-1). Hypothyroidism, esophageal atresia, tracheoesophageal fistula, and bifid uvula are other abnormalities that have been described.

According to the degree of immunodeficiency, clinical manifestations may include predisposition to a wide variety of common and opportunistic infectious diseases. Common findings are recurrent or chronic pneumonia, chronic diarrhea, and candidiasis of the skin and mucosae. Recurrent or severe herpesvirus infections (e.g., herpes simplex virus, cytomegalovirus), *P. jiroveci* pneumonia, and other opportunistic viral, fungal, protozoal, and mycobacterial infections occasionally are observed when immunodeficiency is severe. Fatal graft-versus-host disease may occur if infants receive blood products containing viable lymphocytes, often during surgical correction of their heart defects. Although DiGeorge syndrome is the most common of the cellular immunodeficiencies, with an incidence of 1 in 3000 live births, only a minority of patients (<1%) with DiGeorge syndrome have severe T-cell deficiency (complete DiGeorge syndrome).[80] Most patients develop adequate T-cell numbers and function by 1 year of age and do not have an increased incidence of opportunistic infections (partial DiGeorge syndrome). At Texas Children's Hospital, 20 percent of patients with DiGeorge syndrome and mild T-cell deficiency have an increased incidence of respiratory tract infections.[20]

Pathogenesis

The syndrome is classified as a developmental defect resulting from faulty embryologic development of the third and fourth branchial arches and their derivatives, including parathyroid glands, aortic arch structures, and the thymus gland.[80] Microdeletions of chromosome 22q11 can be demonstrated in more than 90 percent of patients. A few patients have been reported with a deletion in chromosome 10p. Three groups of investigators simultaneously reported that they reproduced all the characteristic features of DiGeorge syndrome, working with mice models bearing the deletion of *Tbx1*, a gene located within the chromosome 22 critical region.[96]

Diagnosis

Hypocalcemia, congenital heart disease, and characteristic facies may lead to suspicion of DiGeorge syndrome in the neonatal period. The microdeletion in chromosome 22q is detected by FISH analysis. Lymphopenia is variable, as well as T-cell deficiency. Determination of naïve T-cell number and a proliferative response to

mitogens allows a better assessment of the degree of immunodeficiency. Quantitative serum immunoglobulin determinations often are normal, but antibody responses after immunization might be decreased. Imaging studies may show absence of the thymic shadow. It should be taken into consideration that a significant group of patients with DiGeorge syndrome are totally or partially thymectomized while heart surgery is performed for repair of their characteristic conotruncal cardiac malformations.

Treatment and Prognosis

Initial management should focus on the treatment of hypocalcemia and the surgical correction of congenital heart disease. Immunoglobulin replacement therapy and antibiotic prophylaxis should be considered for patients with recurrent infections. Children with very low $CD4^+$ T-cell counts or evidence of significant cellular immune dysfunction should receive prophylaxis for *P. jiroveci* pneumonia. Infections should be recognized early and treated promptly. Only irradiated, cytomegalovirus-negative blood products and inactivated vaccines should be administered. Several small retrospective studies have suggested that children with partial DiGeorge syndrome and normal or only mildly decreased $CD4^+$ T-cell counts may receive live vaccines without serious adverse events.[9,53,60] However, the safety of live vaccination has not been well established and is currently not recommended. Approximately 8 percent of patients develop autoimmunity, frequently cytopenias and hypothyroidism. Therapeutic options for DiGeorge syndrome patients with severe immunodeficiency are bone marrow transplantation and, experimentally, thymus transplantation.[48]

Wiskott-Aldrich Syndrome

Clinical Features

Wiskott-Aldrich syndrome is an X-linked disorder classically characterized by recurrent infection, bleeding, and eczema. However, only a minority of patients have this classic triad of features, and some patients only have infectious manifestations.[54,55] At presentation, patients have a hemorrhagic diathesis, followed by recurrent otitis media or pneumonia caused by encapsulated bacteria (e.g., *S. pneumoniae*, *H. influenzae*). Septicemia, meningitis, and other serious systemic bacterial infections also may occur. Common opportunistic pathogens include *Candida*, cytomegalovirus, other herpesviruses, and *P. jiroveci*.

Individuals with Wiskott-Aldrich syndrome often have low platelet counts. A unique feature is the presence of small platelets (low mean platelet volume). As a consequence, thrombocytopenia leads to bruises and gastrointestinal bleeding in the first months of life. Life-threatening gastrointestinal or intracranial hemorrhage also may occur. Eczematous lesions are generalized and prone to bacterial superinfection.

Patients with Wiskott-Aldrich syndrome have a high incidence of autoimmune disorders.[54] Hemolytic anemia, a juvenile rheumatoid arthritis-like condition, and large- or small-vessel vasculitis have been reported. Some patients develop autoimmune thrombocytopenia as their disease progresses. Lymphoid malignancies, especially non-Hodgkin lymphomas involving the brain, have been reported.

Pathogenesis

The *WAS* gene is mutated in individuals with Wiskott-Aldrich syndrome[24] and maps to the X chromosome. This gene encodes a protein that is expressed in lymphocytes and platelets and is involved in cytoskeletal organization and formation of pseudopodia.[83] The immunologic synapse is not well formed as a result of a defective WAS protein, resulting in poor cognate interaction between T cell and B cell. X-linked thrombocytopenia without or with only mild immunodeficiency and eczema has been found to be caused by *WAS* mutations that allow partial protein expression.[91]

Diagnosis

Wiskott-Aldrich syndrome should be suspected in an infant with thrombocytopenia and small volume platelets, which is best assessed by examining a peripheral blood smear, because automatic hematology cell counters report average values. The presence of eczema supports the diagnosis. Serum immunoglobulin concentrations are variable, with the most typical pattern showing normal IgG, increased IgA and IgE, and decreased IgM. Antibody responses to protein antigens (e.g., tetanus toxoid) usually are normal, but responses to polysaccharides (e.g., *S. pneumoniae*, *H. influenzae* type b, isohemagglutinins) are absent.

Patients with Wiskott-Aldrich syndrome are anergic on delayed hypersensitivity skin testing. They have near-normal numbers of circulating T cells, and in vitro proliferative responses to mitogens could be normal. However, responses to specific antigens are decreased. Monocytes exhibit abnormal chemotaxis and poor antibody-dependent cellular cytotoxicity.

The determination of WAS protein expression and the sequencing of the *WAS* gene is available in specialized research laboratories.

Treatment and Prognosis

Hematopoietic stem cell transplantation commonly results in normalization of cellular immunity, specific antibody responses, and platelet count. Splenectomy should be considered for severe thrombocytopenia when bone marrow transplantation is not available and may improve quality of life. Daily antibiotic prophylaxis directed against *S. pneumoniae* and *H. influenzae* should be indicated for patients who have undergone splenectomy. Acute infections should be treated aggressively. Immunoglobulin replacement therapy is indicated for patients with recurrent bacterial infections.

The prognosis of Wiskott-Aldrich syndrome has improved in recent years, with some patients surviving to adulthood. Infection, malignancy, and hemorrhage are the leading causes of death.[54]

Ataxia-Telangiectasia

Clinical Features

Ataxia-telangiectasia is characterized by cerebellar ataxia, oculocutaneous telangiectases, variable immunodeficiency with frequent infections, and a high incidence of malignancy.[51] Neurologic signs and symptoms dominate the clinical picture. Ataxia usually becomes evident when the child is approximately 1 year of age. Progressive choreoathetosis, myoclonic jerking movements, and oculomotor abnormalities subsequently develop, resulting in severe disability. Telangiectases appear on the bulbar conjunctivae, usually in patients between 2 and 5 years of age (see Fig. 67-2). They subsequently appear on the nasal bridge, ears, and other areas of sun exposure or trauma. Other cutaneous manifestations include café-au-lait spots, vitiligo, and prematurely gray hair. Recurrent infections are a major feature of ataxia-telangiectasia in most patients. Sinopulmonary infections predominate; however, systemic infections are rare in spite of the immunologic abnormalities. Organisms commonly implicated include *S. pneumoniae* and *H. influenzae*. Over 15 percent of patients with ataxia-telangiectasia develop neoplasias, from which non-Hodgkin lymphomas and leiomyomas occur most frequently. Carcinomas (especially of the stomach) occur commonly among adults with ataxia-telangiectasia.[51]

Pathogenesis

Ataxia-telangiectasia is inherited in an autosomal recessive manner. The defective gene *(ATM)* responsible for the disorder maps to chromosome 11.[69] One domain of the ATM protein appears to be important in numerous cellular responses, including cytokine signaling. Another region of the protein is involved in DNA repair. Disease manifestations result from a major defect in one or more DNA repair mechanisms. Impairment of normal mechanisms of DNA rearrangements required for expression of the T-cell receptor genes and immunoglobulin heavy-chain genes on chromosomes 7 and 14 explains the observed immunodeficiency.

Diagnosis

A clinical diagnosis of ataxia-telangiectasia is possible when the disease is fully manifested. Increased serum α-fetoprotein concentrations are observed in essentially all patients older than 6 months of age. Most patients have deficiencies in serum IgA and IgE. Specific antibody responses usually decline as the patient ages. Most patients have serum IgM in a monomeric 7S form rather than the usual pentameric 19S molecule. Common manifestations of immunodeficiency include delayed hypersensitivity skin test anergy and decreased lymphocyte proliferative responses to mitogens and antigens. The sequencing of the *ATM* gene is available in specialized laboratories.

Treatment and Prognosis

No specific treatment is available for ataxia-telangiectasia because of the pathologic processes involving multiple body systems. Infections should be treated promptly with oral or parenteral antibiotics. Continuous prophylactic antibiotic therapy may be of benefit to individual patients. Immunoglobulin replacement therapy is reserved for patients with recurrent infections and abnormal specific antibody responses.

The clinical course and prognosis of ataxia-telangiectasia are variable. Death from chronic pulmonary disease or malignancy occurs commonly during the second or third decade of life.

Severe Combined Immunodeficiency

Clinical Features

Infants with SCID are usually diagnosed during their first few months of life because of recurrent or severe infections.[79] In the neonatal period they may have a rash produced by a graft-versus-host reaction induced by maternal lymphocytes. Recurrent pneumonia and persistent or severe viral infections caused by respiratory syncytial virus, parainfluenza virus, or rhinovirus are clues that an infant may have SCID. Infants with SCID may also have severe, disseminated infection with cytomegalovirus, especially if accompanied by very high plasma viral load and hemolytic anemia. In addition, unusual reactions to live virus vaccines, including disseminated varicella after Varivax or measles-mumps-rubella-varicella (MMRV) vaccine administration, and persistent infection with vaccine strains of rubella and measles virus may occur in some patients with SCID. Disseminated infection with BCG after BCG vaccine also may occur in infants with SCID. In addition, persistent oral and cutaneous candidiasis are common occurrences, as are chronic diarrhea and failure to thrive. Septicemia and other serious systemic bacterial infections also occur. Causative organisms include routine pathogens (e.g., *S. pneumoniae*, *H. influenzae* type b) and more unusual organisms. Life-threatening opportunistic infections, including *P. jiroveci* pneumonia, frequently occur early in infancy.

Pathogenesis

SCID represents a heterogeneous group of genetic disorders having in common a profound immunodeficiency with failure of both cellular and humoral immune function. Various types of SCID have been defined on the basis of enzymatic, genetic, and immunologic criteria (Table 67-7), including reticular dysgenesis, with impaired lymphoid, myeloid, and erythroid differentiation; absence of T-cell and B-cell differentiation; selective defects of T-cell differentiation; and purine metabolism defects (e.g., adenosine deaminase deficiency). Autosomal and X-linked recessive inheritance patterns have been recognized. Individuals with X-linked SCID have a defect in the γ chain of the IL-2 receptor, and it is the genetic defect identified in about half of SCID patients.[88] This protein is a functional component of the receptors for IL-4, IL-7, IL-9, IL-15, and IL-21 and is essential for development of T cells and natural killer cells.[45]

TABLE 67-7 **Types of Severe Combined Immunodeficiency (SCID)**

Type	Defect
Reticular dysgenesis	Defective stem cell maturation
RAG1, RAG2 deficiency, Omenn syndrome	Rearrangement of B- and T-cell receptor genes
Artemis deficiency	Rearrangement of B- and T-cell receptor genes
X-linked SCID (common γ-chain)	Signaling for IL-2, IL-4, IL-7, IL-15, and IL-21
JAK3 deficiency	Cytokine signaling
IL-7 receptor deficiency	Signaling for IL-7
CD3D or *CD3E* deficiency	*CD3D* or *CD3E* signaling
PTPRC (*or CD45*) deficiency	Signaling for *PTPRC,* cell activation
Coronin 1A	Defective thymic egress of T cells
Adenosine deaminase deficiency	Metabolite (dATP) toxicity to lymphocytes
MHC class I deficiency	Defect in transporter proteins TAP-1, TAP-2
MHC class II deficiency	Defects in transcription factors RFXAP, RFX5, RFXANK, and transactivator CIITA

MHC, major histocompatibility complex.

Diagnosis

Infants with SCID typically lack palpable lymph nodes, visible tonsils, and radiographic evidence of a thymus gland. Lymphopenia is often identified.[88] Some patients have panhypogammaglobulinemia, whereas others have depressed concentrations of only one or two immunoglobulin isotypes. Antibody responses almost always are profoundly impaired or absent. Lymphocyte monoclonal phenotyping may reveal the presence of circulating mature nonfunctional B cells. Particularly in boys with X-linked SCID and JAK3-deficient SCID, B cells may account for all circulating lymphocytes. Circulating T-cell counts are diminished (<10% of normal range) in most patients with SCID. Delayed hypersensitivity skin test anergy is found, and lymphocyte proliferative responses to mitogens and antigens are severely depressed. Testing for a specific genetic defect should be pursued, and a genetic evaluation of immediate relatives for carrier status is recommended for genetic counseling purposes. Biochemical tests for adenosine deaminase and purine nucleoside phosphorylase levels and enzymatic activities are available in specialized laboratories.

Treatment and Prognosis

Hematopoietic stem cell transplantation (HSCT) is the treatment of choice for most patients with SCID.[18] Prognosis is poor for patients without definitive therapy. HSCT performed with HLA-matched related donors have a survival rate of over 95 percent. However, most patients do not have such a donor available and receive an HLA-haploidentical transplant. Survival rates with these donors are variable but have increased significantly with advances in antimicrobial therapy and intensive care. This survival rate can increase to over 95 percent if the SCID is detected early and HSCT is performed before 3.5 months of age, before infections and organ damage occur. HLA-matched unrelated donors and HLA-matched cord blood have been increasingly used for different forms of SCID, accompanied with different chemotherapy regimens for myeloablation. As an alternative due to the high mortality and morbidity associated with HSCT, European investigators have reported success in experimental gene therapy trials for X-linked SCID. Using autologous $CD34^+$ stem cells carrying the correct version of the gene, they were able to restore humoral and cellular immunity in 12 of 14 affected patients.[34] Unfortunately, 4 patients developed leukemia that was in part caused by the gene therapy vector. Three of the 4 patients survived after receiving conventional antileukemia therapy. New developments to reduce the risk for leukemia in gene therapy are underway.[28] Enzyme replacement using bovine-derived pegylated adenosine deaminase and gene therapy[18,29] have been used for treatment of SCID resulting from adenosine deaminase deficiency. Pegylated adenosine deaminase therapy has demonstrated efficacy to increase lymphocyte counts and provide adequate immunity in most affected patients. Some of them ultimately develop "resistance" to the drug in the form of eliciting neutralizing anti–adenosine deaminase antibodies or simply demonstrating a decrease of lymphocyte counts. Positive results of experimental gene therapy trials for SCID caused by adenosine deaminase deficiency with the restoration of both cellular and humoral immunity have been reported in more than 30 patients using a protocol that included withdrawal of exogenous adenosine deaminase and reduced myeloablation.

Miscellaneous Cellular Immune Deficiencies

Many other disorders of cellular immunity have been described. Particularly noteworthy are disorders characterized for dysregulation of the immune system with autoimmune inflammation. The X-linked lymphoproliferative (XLP) syndrome represents a defect in control of Epstein-Barr virus infection. Mutations in the SLAM-associated protein (SAP), a factor involved in the signal transduction of T cells, have been identified to cause XLP syndrome. The absence of this protein affects the interaction of T and B cells, leading to an inability to control B-cell proliferation caused by Epstein-Barr virus infection.[30,66,70] At presentation, patients may have severe and often fatal infectious mononucleosis or B-cell lymphoma.

Chronic mucocutaneous candidiasis is a condition characterized by chronic, severe infection with *Candida* spp. It affects the mucous membranes, skin, and nails

and often is associated with autoimmune polyendocrinopathy, in which case it is named autoimmune polyendocrinopathy ectodermal dystrophy (APECED).[38] T-cell numbers and function are usually normal, but most patients do not manifest delayed hypersensitivity skin test responses to *Candida*, and their lymphocytes fail to proliferate in response to *Candida* antigen in vitro. In cases with APECED, deleterious mutations have been found in the autoimmune regulator *(AIRE)* gene. This gene promotes the expression of many self-antigens in the thymus, facilitating the development of immune tolerance during lymphocyte differentiation. Another autoimmune endocrinopathy with immunodeficiency is IPEX (immunodeficiency, polyendocrinopathy, enteropathy, X-linked). IPEX results from mutations in the *FOXP3* gene and is characterized by lack of T regulatory cells and clinically by eczema, chronic diarrhea, diabetes mellitus, and other hormone deficiencies due to autoimmunity and decreased immunologic tolerance.[42]

Mutations in the IFN-γ receptor genes have been demonstrated in patients with severe infections caused by atypical mycobacteria.[37,67] Patients with a mutation in *IL12RB2* or in *IL12B* have also shown increased susceptibility to mycobacterial disease and disseminated nontuberculous mycobacterial infection.[5]

NEMO deficiency is a primary immunodeficiency caused by specific missense mutations in the *IKBKG* (also known as nuclear factor kappa B [NFκB]-enhancing modulator or NEMO) gene, located on chromosome Xq28.[78,98] The gene participates in signal transduction mediated by NFκB. Most mutations in *IKBKG* are lethal for male fetuses, and female carriers of these mutations may have incontinentia pigmenti. The surviving male patients with specific missense mutations have anhidrotic ectodermal dysplasia, conical teeth (Fig. 67-5), low IgG, low IgA, normal or increased IgM levels, and decreased T-cell proliferative responses to mitogen and antigen stimuli.[61]

FIGURE 67-5 ■ Conical teeth characteristic of incontinentia pigmentosa with immunodeficiency due to defects in the *IKBKB* gene (NEMO defect). (See companion Expert Consult website for color version.)

PRIMARY COMPLEMENT DEFICIENCIES

Clinical Features

Three types of complement function deficiency are associated with increased susceptibility to infections: deficiency of opsonic activity of complement proteins, deficiency of the complement lytic proteins, and deficiency of the mannose-binding lectin pathway.[13,75] Patients with deficiencies of early-acting complement components (e.g., C3, C1, C4, C2) are particularly susceptible to infection with encapsulated bacteria, including *S. pneumoniae* and *H. influenzae;* in addition, they have an increased risk for developing autoimmune disorders such as systemic lupus erythematosus.[13] *Neisseria meningitidis* is the most important bacterial pathogen observed in patients with deficiencies of terminal complement components (C5 through C9).[7] Recurrent episodes of septicemia and meningitis are especially common. Although patients with deficiencies of late-acting complement components are at increased risk for developing meningococcal septicemia and meningitis, they appear to suffer lower rates of morbidity and mortality than immunologically normal individuals with systemic meningococcal infection. The frequency of primary complement deficiencies among patients with invasive meningococcal disease is 5 to 10 percent[7,50]; however, the likelihood of having complement deficiency increases dramatically (31%) among individuals who have had more than one episode of invasive disease. A deficiency of opsonization in children with recurrent pyogenic infections and failure to thrive led to the recognition of the mannose-binding lectin pathway deficiencies. The clinical characteristic of these patients is the increased frequency of pyogenic infections; however, the essential role of the mannose-binding lectin pathway is controversial owing to the high proportion of healthy individuals with mannose-binding lectin deficiency.[35]

Pathogenesis

Various gene defects are responsible for the many distinct primary complement deficiencies. The particular bacteria that causes infection may indicate the missing component in host defense. For example, C3b, the major cleavage product of C3, is an important opsonic ligand that promotes ingestion and killing of bacteria. As a consequence, patients with C3 deficiency have increased susceptibility to bacterial infections (e.g., *S. pneumoniae*, *H. influenzae*), for which opsonization is the primary mechanism of host defense. Individuals with deficiencies of C1, C4, or C2 also have increased susceptibility to these encapsulated bacteria because these components are necessary for activation of C3 through the classical pathway. Activation of terminal complement components C5, C6, C7, C8, and C9 results in assembly of the membrane attack complex C5b-9, a multicomponent macromolecule capable of

bactericidal activity. Only gram-negative bacteria are susceptible to this bactericidal effect. Infections in patients with deficiencies of terminal complement components are therefore limited to gram-negative bacteria, such as *N. meningitidis*.

Diagnosis

When the history of infections is suggestive, the screening test used for complement deficiencies is the CH50 assay, which depends on the activity of all numbered components of the classical complement pathway from C1 through C9. Specific immunochemical and functional testing can be performed for identifying the deficient component, when CH50 test results suggest a complement component deficiency.

Treatment and Prognosis

No specific therapy exists for primary complement deficiencies. Meningococcal vaccine is recommended for children with terminal complement component deficiencies. Antibiotic prophylaxis and vaccines for other encapsulated organisms may be beneficial.

PRIMARY PHAGOCYTE DEFICIENCIES

The primary phagocyte deficiencies are a heterogeneous group of disorders having in common a susceptibility for frequent infections, resulting from a decreased number of phagocytic cells (e.g., neutropenia) or because of impaired adhesion, chemotaxis, opsonization and phagocytosis, or intracellular killing (Table 67-8). Infections resulting from quantitative or qualitative phagocyte deficiencies tend to be prolonged and recurrent, with a response to antibiotic therapy that is slower than expected. Common pathogens include *S. aureus*, *P. aeruginosa*, enteric gram-negative bacteria, and certain fungi (e.g., *Candida* spp., *Aspergillus* spp.).

TABLE 67-8 **Primary Phagocyte Deficiencies**

Quantitative Defects
Infantile agranulocytosis
Familial granulocytopenia
Cyclic neutropenia
Qualitative Defects
Adhesion Defects
Leukocyte adhesion deficiency
Type I, β-integrin deficiency
Type II, fucose-transporter deficiency
Type III, *FERMT3* deficiency
Intracellular Killing Defects
Chronic granulomatous disease
X-linked
Autosomal recessive
Glucose-6-phosphate dehydrogenase deficiency
Myeloperoxidase deficiency
Chédiak-Higashi syndrome
Griscelli syndrome

Quantitative Phagocyte Abnormalities

Primary quantitative phagocyte deficiencies can be observed as solitary defects or in association with other disorders (e.g., Shwachman syndrome). Infantile agranulocytosis (i.e., Kostmann syndrome) is an autosomal recessive disorder characterized by arrest of granulocyte maturation, markedly decreased numbers of circulating granulocytes, and severe infection. The more benign familial granulocytopenia syndrome manifests at various ages from infancy to adulthood, usually with indolent infections of the skin and soft tissues.

Cyclic neutropenia is an autosomal dominant defect of myelopoiesis due to mutation in the leukocyte elastase *(ELANE)* gene in which periodic disappearance of granulocytes from the circulation occurs.[15] Early granulocyte precursors are present in the bone marrow during periods of granulocytopenia, suggesting transient maturation arrest. Periods of granulocytopenia usually last 5 to 7 days and occur at 14- to 35-day intervals. The length of the cycle generally is constant for any given individual. Fever, malaise, aphthous stomatitis, and skin and soft tissue infections often are observed during periods of granulocytopenia.

Some of the primary quantitative phagocyte deficiencies, particularly familial granulocytopenia and cyclic neutropenia, respond to therapy with recombinant granulocyte colony-stimulating factor.[27]

Chronic Granulomatous Disease

Clinical Features

Patients with CGD have infections that begin during infancy and recur throughout their lives. Occasionally, patients have a relatively mild disease course and come to medical attention only during adolescence or adulthood. A history of suppurative lymphadenitis, soft tissue abscesses, pneumonia, lung abscess, hepatic abscess, perirectal abscesses, and osteomyelitis suggests CGD.[72] Infections in patients with CGD may progress with few symptoms, and the erythrocyte sedimentation rate and C-reactive protein value may be useful to detect active infection.

Patients with CGD generally have infections caused by catalase-positive bacteria and fungi. *S. aureus* accounts for almost one third of all infections of determined cause. *Nocardia*, *S. marcescens*, *Pseudomonas* spp., *Burkholderia cepacia*, and certain enteric gram-negative bacilli also are common findings. Fungi, especially *Aspergillus* spp., account for nearly one fifth of all defined infections in patients with CGD (Fig. 67-6).[11]

Patients with CGD often have poor wound healing. Granulomatous obstructive lesions of the urinary and gastrointestinal tracts have been reported. Granulomatous bowel involvement resembles Crohn disease. Corticosteroid therapy may be effective in relieving these sometimes life-threatening lesions.[44] A small percentage of boys with X-linked CGD have the McLeod blood

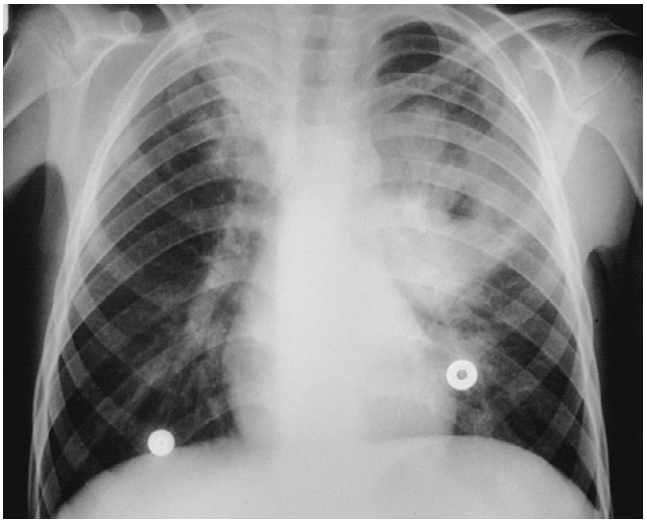

FIGURE 67-6 ■ Chest radiograph of a 10-year-old boy with chronic granulomatous disease shows a left-sided pulmonary infiltrate and cavitary lung lesion. Biopsy revealed an *Aspergillus fumigatus* infection.

phenotype, characterized by absence of the Kell antigen in red blood cells as a consequence of a contiguous gene deletion, which results in difficult crossmatching for blood transfusion and the potential for hemolytic transfusion reactions.[16]

Pathogenesis

X-linked and autosomal recessive forms of CGD have been described. The various gene defects result in abnormalities of membrane or cytosolic components of the nicotinamide adenine dinucleotide phosphate oxidase complex system. Despite the genetic heterogeneity, all individuals with CGD have in common the failure of the cellular respiratory burst, which ordinarily accompanies phagocytosis and various soluble stimuli. As a consequence, oxygen-derived microbicidal factors are not formed, resulting in impairment of intracellular killing of phagocytized microorganisms.

Diagnosis

The diagnosis of CGD has historically been made with the NBT dye test.[51] Neutrophils from normal individuals show 100 percent reduction of NBT, asymptomatic carriers show 20 to 90 percent reduction, and patients with CGD show essentially no dye reduction. In patients with mild forms of the disease, the NBT test result may be normal. A more sensitive method to measure hydrogen peroxide production is based on chemiluminescence of DHR on activation, detected by flow cytometry and increasingly used as a confirmatory test of the disease, replacing the NBT dye test.

Treatment and Prognosis

Specific microbiologic diagnosis of infections should be established whenever possible. Empirical therapy is directed against the organisms known to be common causes of infection: *S. aureus*, *Pseudomonas* spp., and enteric gram-negative bacilli. Surgical drainage or débridement of sites of infection often is required. Anecdotal reports suggest beneficial effects of granulocyte transfusions in patients with CGD and serious bacterial or fungal infections. HSCT has been used successfully,[17,49] and gene therapy trials for X-linked CGD in humans have resulted in gene-corrected, autologous granulocytes detectable for more than 30 months after treatment, with resolution of chronic infections.[58] However, the oxidase activity of the gene-corrected cells had progressively decreased, by mechanisms of "gene silencing."

Antibiotic prophylaxis with cotrimoxazole reduces the frequency of bacterial infections in patients with CGD.[72] Itraconazole and other antifungal agents given as prophylaxis may be effective for the prevention of *Aspergillus* infections, which are usually severe and difficult to eradicate. The administration of IFN-γ, given by subcutaneous injection three times weekly, reduces the incidence of serious infections in CGD by as much as two thirds without causing major side effects. Patients should be educated about not performing activities that expose themselves to environments containing mold spores, such as mulching or raking leaves. The prognosis of CGD has improved remarkably during the past several decades and now most patients survive to adulthood.

Leukocyte Adhesion Deficiency

Clinical Features

Patients with LAD suffer severe and recurrent bacterial infections of the skin and soft tissues, mucosal surfaces, and gastrointestinal tract, often beginning during early infancy. Common pathogenic microorganisms include staphylococci and *Pseudomonas* spp. Infants with the severe phenotype may have delayed separation of the umbilical cord secondary to omphalitis. Cutaneous infections show as inflamed tissues but without pus, owing to a defect in leukocyte extravasation, and may become necrotic, resembling ecthyma gangrenosum or pyoderma gangrenosum. Poor wound healing also is observed. Individuals surviving infancy typically develop severe gingivitis and periodontitis with progressive alveolar bone loss (see Fig. 67-3).

Marked granulocytosis is a hallmark of LAD. Circulating granulocyte counts may range between 15,000/mm^3 and 75,000/mm^3, even in the absence of infection; and counts of 100,000/mm^3 or greater are common findings during episodes of infection.

Pathogenesis

LAD type I is an autosomal recessive disorder that maps to chromosome 21. Neutrophils from individuals with LAD are defective in their expression of several surface glycoproteins known as the leukocyte-integrin complex. These molecules are critical for adhesion-dependent functions, and their absence is responsible for defects in

leukocyte adherence, chemotaxis, and phagocytosis. The severity of infectious complications of LAD is related directly to the degree of CD18 expression.[84] Patients with the severe clinical phenotype have undetectable expression of these complexes on their phagocytes, whereas individuals with the moderate phenotype generally have 2 to 8 percent expression, explained by missense gene mutations allowing surface expression of a defective protein.

A second form of LAD was described in patients with craniofacial dysmorphism, neurologic deficits, recurrent respiratory tract infections, and marked granulocytosis.[25] Unlike those of patients with LAD type I, neutrophils from patients with LAD type II had normal surface expression of CD18. The molecular basis for the phagocyte dysfunction is a defect in the fucose transporter influencing the glycosylation of sialyl-Lewis X, a carbohydrate ligand for the endothelial adhesion molecules E-selectin and P-selectin. A third form of LAD has been described, characterized for a deficiency of all β integrins, owing to a deficiency of FERMT3, a signal transducer necessary for integrin stabilization.

Diagnosis

The diagnosis of LAD type I is made by flow cytometry using fluorescence-labeled monoclonal anti-CD11/CD18 antibody.[84] In vitro studies reveal abnormalities of phagocyte adherence, chemotaxis, and phagocytosis. Individuals with LAD type II have similar phagocyte function abnormalities, with normal expression of CD18 and downregulation of selectins. LAD type III is characterized by altered expression of all β integrins.

Treatment and Prognosis

Intercurrent bacterial infections in patients with LAD must be treated aggressively with prolonged courses of parenteral antibiotics. Antibiotic prophylaxis and universal hygiene measures are recommended. Although survival to adulthood is described, almost one half of affected individuals die before reaching the second decade of life. Administration of fucose normalizes leukocyte function in LAD type II. Bone marrow transplantation offers the best hope for long-term survival.[82]

Other Primary Phagocyte Deficiencies

A variety of other defects of phagocyte chemotaxis, phagocytosis, and intracellular killing have been described.[87] The Chédiak-Higashi syndrome is a rare autosomal recessive disorder characterized by partial oculocutaneous albinism, rotatory nystagmus, and peripheral neuropathy. Affected individuals develop recurrent serious or life-threatening infections caused by a wide variety of bacteria. In the accelerated phase of the illness, hepatosplenomegaly, lymphadenopathy, lymphocytic infiltration of multiple organs, and unexplained febrile illnesses are common occurrences. Giant granules are found in numerous different cell types, including leukocytes, in the body. Neutrophils exhibit defective chemotaxis and abnormal bactericidal activity.

Hyperimmunoglobulinemia E (hyper-IgE syndrome, Job syndrome, Buckley syndrome) is characterized by markedly elevated serum IgE levels, eczema, recurrent staphylococcal abscesses, sinusitis, and otitis media. Coarse facial features are common findings. In addition to staphylococcal abscesses, recurrent pneumonia with bronchiectasis and pneumatoceles and mucocutaneous candidiasis are common occurrences. Other observed features include delay of shedding of primary dentition, recurrent bone fractures, scoliosis, and joint hyperextensibility. Hyper-IgE syndrome presents most often as autosomal dominant inheritance and can be diagnosed when the patient or family members have the skeletal manifestations. Mutations in the *STAT3* gene are responsible for this syndrome.[31]

CONCLUSION

Primary immunodeficiencies, once considered rare diseases, are increasingly being diagnosed to explain the high frequency of infections in children. Deleterious mutations in more than 165 genes have been identified to be responsible for primary immunodeficiencies, and several advances have clarified the immunopathogenesis of these conditions. The severity of the immunologic defects ranges from an increase of sinorespiratory tract infections seen in IgG subclass deficiencies to increased susceptibility to opportunistic infections during the first weeks of life, such as in SCID.

Pediatricians should be alert that these diseases should be suspected and investigated in children with infections of unusual severity, frequency, or etiologic organisms, as well as unexplained general symptoms, such as fever or failure to thrive. The initial immunologic screening consists of simple laboratory tests, and prompt referral to the clinical immunologist is warranted when an immunodeficiency is suspected. The management for these disorders has advanced over recent years to remarkably improved care, reflected in the majority of immunodeficient patients surviving to adulthood. Universal neonatal screening for T-cell deficiencies is a public health directive to identify severe defects before damaging infections occur and has proven to help patients avoid potential complications. Curative treatment is available for severe immunodeficiencies in the form of allogeneic HSCT; however, it is not without considerable mortality risk, and cure is not always optimal. Although still experimental, gene therapy has reached the stage of clinical trials for X-linked SCID, adenosine deaminase–deficient SCID, Wiskott-Aldrich syndrome, and CGD, with successful and promising results.

CHAPTER 68

The Febrile Neutropenic Patient

Brian T. Fisher • Lillian Sung

Since chemotherapeutic agents were first administered for the treatment of malignancy, infection has been a cause of significant morbidity and mortality. Initial reports documented an infection-related mortality rate among patients with acute leukemia that was greater than 70 percent.[56,60] In the last 5 decades, chemotherapeutic regimens have been refined, resulting in improved pediatric cancer survival rates.[106,141] However, the immunosuppressive consequences of chemotherapy continue to exist, and infections still account for more than 60 percent of deaths in children receiving intensely myelosuppressive chemotherapy.[29,127]

For many decades, researchers have sought to identify risk factors for infection and to devise risk-stratified therapeutic approaches to reduce infectious mortality rates in patients receiving chemotherapy. Early descriptive pediatric studies confirmed that the depth and duration of neutropenia was a risk factor for developing infection. Further, fever was a frequent and sometimes the only clinical sign indicating the presence of infection in this at-risk population.[60] In these early years, fever in patients with neutropenia prompted an infectious evaluation but empirical antibiotic therapy was not considered the standard of care. Because infection was the most common cause of fever in neutropenic patients and because some patients with fever and neutropenia had rapid progression to death, particularly resulting from *Pseudomonas aeruginosa* bacteremia, empirical therapy was explored. In 1971, Schimpff and colleagues[117] published one of the sentinel experiences of combination empirical therapy with carbenicillin and gentamicin in a series of patients with fever and neutropenia.[117] Their efforts revealed a reduction in infectious mortality with this approach relative to historical controls. Specifically, in the historical control period, when empirical antibiotic therapy was not used, 20 of 22 *P. aeruginosa* infections ultimately resulted in death. This compared to only 4 deaths out of 21 *P. aeruginosa* infections during the study period. Subsequent landmark trials by Pizzo and colleagues[99,101] supported the continuation of empirical antibiotics through the duration of neutropenia and prompted the addition of empirical antifungal therapy in the setting of prolonged fever and neutropenia despite broad-spectrum antibiotic therapy.

In the decades that followed, empirical antibacterial and antifungal therapy has evolved into the standard of care for patients with fever and neutropenia. Clinical practice guidelines from various societies have better standardized the approach to this clinical scenario.[31,46,73,84] Although these guidelines have been useful, they have primarily focused on adult patient populations. This has left pediatricians to apply guidelines that have not accounted for important differences between children and adults presenting with fever and neutropenia.[126] Fortunately, some of the important differences between pediatric and adult fever and neutropenia have been addressed in recent international pediatric fever and neutropenia guidelines.[76] Nonetheless, as noted in the pediatric guidelines, many questions remain surrounding the diagnostic and therapeutic approach to fever and neutropenia. For example, are there ways to improve diagnostic approaches to identify the presence or absence of bacterial and fungal infections, and is prophylactic antimicrobial therapy a useful approach to reducing infection?

This chapter will focus on the epidemiology of fever and neutropenia and approaches for risk stratification that are pertinent to pediatric patients. Additionally, advances in modalities for diagnosing bacterial and fungal infections will be explored. Finally, empirical, preemptive, and prophylactic therapeutic interventions will be reviewed. At relevant points, areas for necessary future investigation will be highlighted. Many other etiologies of neutropenia (e.g., congenital neutropenia) exist,[107] and such patients also will incur periods of fever and neutropenia. However, the importance of fever in these settings varies substantially and thus the focus of this chapter will be on fever in the setting of chemotherapy-induced neutropenia.

EPIDEMIOLOGY

Children receiving chemotherapy often are confronted with at least one episode of fever and neutropenia during the course of their cancer care. The frequency of fever and neutropenia varies depending on factors such as type and extent of malignancy, intensity of chemotherapy, and duration of neutropenia. An estimated 10 to 50 percent of patients with solid tumors will suffer at least one episode of fever and neutropenia. The incidence of fever and neutropenia increases to 80 percent in patients with hematologic malignancy and approaches 100 percent in some higher-risk populations.[46,131]

Bacterial Pathogens

Fever in the setting of neutropenia often is the initial and potentially the only clinical sign of a bacterial, fungal, or

viral infection. Of patients in whom a pathogen is identified, bacteria predominate. In a landmark study evaluating 793 pediatric cancer patients with fever and neutropenia, Pizzo and colleagues[100] found that 87 percent of patients with a microbiologically documented infection suffered from a bacterial infection. Recent epidemiologic studies specific to pediatric fever and neutropenia have suggested a reduction in the proportion of episodes attributable to bacteria. However, despite the reduction, bacterial pathogens still accounted for the majority of all identified pathogens.[21,54]

Early reports on the epidemiology of these bacterial infections highlighted gram-negative pathogens as the predominant cause of infection in neutropenic children and adults. *Escherichia coli*, *P. aeruginosa*, and *Klebsiella* spp. were the three most commonly isolated pathogens.[120] Subsequently, toward the end of the 1980s, gram-positive pathogens were being increasingly recognized as an important source of fever of neutropenia[34,139] and soon thereafter gram-positive pathogens were found to be more common than gram-negative organisms.[145] This shift in pathogens has been attributed to increased use of central venous lines, a greater prevalence of mucositis, and prophylactic regimens with predominantly gram-negative activity. Additionally, escalation to more intensive chemotherapy regimens, such as those containing high-dose cytarabine, have resulted in more impressive mucositis, which has contributed to increases in specific pathogens such as viridans group streptococci.[127]

The spectrum of bacterial pathogens depends on specific chemotherapy, use of antimicrobial prophylaxis, and setting. Table 68-1 displays the distribution of bacterial infections across various international pediatric oncology cohorts.[11,21,54,75] Variation in the frequency in isolating a bacterial pathogen is apparent. This is likely secondary to variation in patient makeup of each cohort and variation in diagnostic testing practices. With the exception of the Malaysian cohort, the predominance of gram-positive pathogens has persisted in pediatric oncology cohorts, consistent with data published toward the end of the previous century. Among the gram-positive pathogens, viridans group streptococci, *Staphylococcus aureus*, and coagulase-negative staphylococci are predominant. As for gram-negative pathogens, *E. coli*, *P. aeruginosa*, and *Klebsiella* spp. are still most commonly identified.[11,21,54,75]

Fungal Pathogens

The likelihood of an invasive fungal infection during an episode of fever and neutropenia varies depending on risk factors, as discussed in more detail later. Generally, fungal pathogens are considered the etiology of fever and neutropenia when these two clinical signs are concurrently prolonged or when fever is recurrent during the same episode of neutropenia. Defining the epidemiology of an invasive fungal infection in specific patient populations can be challenging. Published guidelines on classifying the likelihood of an invasive fungal infection have been helpful in standardizing reporting of such infections[32]; however, limitations in diagnostic modalities for identifying an invasive fungal infection persist, and thus published infection rates are likely underestimated. Despite these challenges, prospective multicenter data have documented an invasive fungal infection rate nearing 6 percent of children hospitalized with fever and neutropenia.[138] *Candida* spp. are the most commonly isolated fungal pathogens, likely related to the frequent existence of *Candida* as a commensal organism on the skin and mucosal surfaces.[39] Compromise of these important anatomic barriers (e.g., mucositis) can result in invasive candidiasis. Additionally, *Candida* spp. can infect central venous catheters, which are commonly present in children with cancer. Although mortality data specific to candidiasis in pediatric oncology patients are limited, the attributable mortality of invasive candidiasis in all pediatric patients has been estimated to be 10 percent.[143]

Invasive mold infections are less common but still extremely important pathogens given the poor outcomes related to these infections. In a contemporary pediatric oncology single center observational cohort, only 54 percent of patients with invasive mold infections responded to therapy in the first 12 weeks from diagnosis and 31 percent of these infections resulted in death within the same time period.[49] Among the mold pathogens, *Aspergillus* spp. are most common, followed by *Mucorales* and *Fusarium* spp.[49,127]

Viral Pathogens

Owing to advancement in viral diagnostic methodologies, multiple publications have attempted to delineate

TABLE 68-1 **Distribution of Bacterial Pathogens in Selected Pediatric Oncology Cohorts**

Author/Year	Ariffin[11] 2002	Lehrnbecher[75] 2004	Castagnola[21] 2007	Hakim[54] 2009
Study location	Malaysia	Germany	Italy	United States
Patient type	Any malignancy	AML	Leukemia, solid tumor, or allogeneic HSCT	Any malignancy
Clinical scenario	Fever and neutropenia	Fever with and without neutropenia	Fever and neutropenia	Fever and neutropenia
Infection episodes (total patients)	762 (513)	855 (304)	614 (NA)	337 (337)
Bacterial pathogen isolation N (%)	270 (35.4%)	252 (29.5%)	97 (15.8%)	54 (16%)
Gram positive pathogens n (%)	103 (38.1%)	203 (80.6%)	57 (58.8%)	31* (57%)
Gram negative pathogens n (%)	167 (61.9%)	49 (19.4%)	40 (41.2%)	23 (43%)

* Includes seven episodes of *Clostridium difficile* infection.
AML, Acute myeloid leukemia; *HSCT,* hematopoietic stem cell transplantation; *N/A,* not available.

TABLE 68-2 **Frequency of Viral Respiratory Pathogens at Presentation for Fever and Neutropenia**

Author/Year	Long[77] 1987	Arola[13] 1995	Christensen[24] 2005	Koskenvuo[71] 2008
Study duration	5 yr	17 mo	12 mo	5.5 yr
Patient type	Leukemia, solid tumors	Any malignancy	Any malignancy	Leukemia
Clinical scenario	Suspicion of virus	Fever	Fever	Fever
Total patients (episodes)	200 (not reported)	32 (75)	66 (250)	51 (138)
Testing methods	Culture, immunofluorescence	Culture, antigen, and antibodies	PCR	Culture, antigen, and PCR
Respiratory virus isolation rate	148 (N/A)	28 (37%)	19 (8%)*	61 (59%)
Bacteremia plus virus isolation	Not reported	None	Not reported	13%

the attribution of fever and neutropenia events to viral pathogens. Table 68-2 displays the frequency of recovered viral upper respiratory tract pathogens in pediatric patients with fever with or without symptoms of a viral infection.[13,24,71,77] Although these studies were not limited to patients with fever and neutropenia, a majority of the patients had concomitant neutropenia. The frequency of laboratory-confirmed viral respiratory tract infection ranged from 8 to 59 percent. Although some authors suggest routine comprehensive viral testing at the time of presentation,[24] the utility of routine viral testing is not clear. First, ideally the identification of a viral pathogen should allow for discontinuation of broad-spectrum antibiotics in the febrile and neutropenic patient. However, bacterial and viral infections are not mutually exclusive, with as many as 13 percent of patients with a viral pathogen suffering a simultaneous bacteremia.[71] Second, the evolution in the availability of viral polymerase chain reaction testing may result in detection of virus well after symptom resolution. Finally, only a few antiviral agents are available for the treatment of some of these viral pathogens, and their effectiveness is not clearly delineated. Viral testing should be limited to patients in whom positive results would result in a change in management such as de-escalation of antibiotic therapy, initiation of an appropriate antiviral therapy (e.g., neuraminidase inhibitor for influenza), or institution of appropriate isolation precautions.

Fever and Neutropenia of Unknown Origin

Despite evaluation, many patients have negative cultures and do not have a clinically evident site of infection. This presentation is often referred to as *fever of unknown origin (FUO).* Although children with FUO can have an occult infection, frequently an infectious pathogen or clinical infection is not present. In a combined pediatric and young adult cohort, Pizzo and colleagues described 306 consecutive episodes of fever and neutropenia in patients cared for at the National Institutes of Health. They found that only 54 percent of patients had an identifiable infection within 7 days from presentation.[101] Despite advances in infectious diagnostic modalities (e.g., more sensitive viral tests), the rates of unidentified etiology of fever and neutropenia in children have remained above 50 percent in the past decade.[11,21,54,75]

RISK STRATIFICATION

Risk Stratification at Initial Presentation

The risk for infection and serious morbidity is highly heterogeneous among patients with fever and neutropenia, and this heterogeneity has resulted in efforts to risk stratify patients. The primary purpose for risk stratification is to guide physicians in deciding when patients can safely be managed with less aggressive interventions such as outpatient management, early discontinuation of antibiotics, and oral therapy and when to intensify diagnostic investigations and therapy for a potential infection. In adults, the predominant risk stratification schema is the Multinational Association for Supportive Care in Cancer Scoring System. Unfortunately, this system incorporates parameters that are not applicable to children, such as lack of chronic obstructive pulmonary disease and age younger than 60 years to determine low-risk status. The inclusion of these parameters limits the applicability of this scoring system to children.[126]

Both retrospective and prospective pediatric cohort studies have been performed to evaluate various clinical prediction rules for designating children as low risk for infection in the setting of fever and neutropenia. These studies have been summarized in two separate meta-analyses.[96,97] Considered collectively, data from these studies support the potential success of implementing a risk stratification protocol. However, each trial used varied patient-relevant factors (e.g., age and malignancy), clinical factors (e.g., timing of chemotherapy, degree of fever, and presence of hypotension), and laboratory parameters (e.g., duration and depth of neutropenia, C-reactive protein value, and platelet count) and had various outcome definitions (e.g., bacteremia, serious infection, and death). Furthermore, attempts to validate six of the pediatric risk stratification schemas in separate populations have resulted in suboptimal performance in contrast to the original study.* Thus, clinicians

*References 5-7, 14, 68, 78, 79, 87, 96, 97, 105, 111, 114, 115.

at individual institutions are left with the challenge of identifying the prediction model that is most consistent with their patient population (rules tend to perform less favorably when applied in different settings) and is most feasible to implement.

The advent of serum biomarkers has resulted in a renewed interest in trying to improve current prediction rules. Investigators have studied the clinical utility of more than 170 different biomarkers, including cytokines, cell surface markers, coagulation system molecules, receptors in various inflammatory cascades, and acute-phase reactants in various pediatric and adult clinical settings.[98] Some biomarkers have emerged as potentially useful tools to guide therapeutic approaches for fever and neutropenia. However, although some biomarkers are often elevated in patients with a bacterial infection, an inability to identify a threshold value for a single biomarker to accurately discriminate between infected and noninfected patients has limited their clinical applicability. Future investigations combining multiple biomarkers with traditional laboratory values and clinical findings may improve the discriminating ability of a pediatric risk prediction rule.

Risk Stratification for Invasive Fungal Infection

The risk stratification prediction rules discussed earlier are specific to risk for outcomes, including bacterial infection at the time of presentation for fever and neutropenia. However, the likelihood of an invasive fungal infection increases as the duration of fever and neutropenia increases, depending on various patient, laboratory, and clinical factors. Children with persistent fever and neutropenia should be further stratified relative to their risk for invasive fungal infection. Although no studies have been specifically dedicated to deriving an invasive fungal infection risk prediction rule in a pediatric cancer cohort, some observational studies have identified important risk factors for invasive fungal infection that can provide general guidelines for risk.[37] Patient populations with reported invasive fungal infection incidence greater than 10 percent include children with acute myeloid leukemia (AML),[52,127,128] relapsed acute lymphoblastic leukemia (ALL),[72] and recipients of an allogeneic stem cell transplantation.[15,37,58,69,134] Additionally, prolonged neutropenia (absolute neutrophil count $\leq 500/mm^3$) or low monocyte counts ($\leq 100/mm^3$) and increased C-reactive protein level of 90 mg/L or greater on the fourth day of fever are laboratory values that have each been associated with invasive fungal infection.[138] Finally, recent prolonged steroid exposure (>10 days) has been repeatedly identified as a risk factor for invasive fungal infection.[37,51,58] Based on these pediatric data, adult and pediatric fever and neutropenia guidelines[47,76] and guidelines for defining invasive fungal infection[32] recommend that patients with fever and neutropenia should be considered at high risk for invasive fungal infection if they have recently received intensive chemotherapy (e.g., AML or relapsed ALL patient) with expected prolonged neutropenia (>7 to 10 days) or recent exposure to prolonged courses of steroids. All other patients should be considered at low risk for invasive fungal infection. This risk stratification is a general guide, and it should be noted that invasive fungal infection has been described in patients who would fall in the low-risk classification.[38] Additional work is necessary to establish specific prediction rules to more accurately discriminate between invasive fungal infection high-risk and low-risk patients.

HISTORY AND PHYSICAL EXAMINATION

Before initiating routine diagnostic testing, a complete history and physical examination should be performed. A comprehensive history can identify important exposures that could alert the physician to consider less common opportunistic infections and direct early additional diagnostic testing. The history should include details about symptoms other than fever, adherence to current medications (especially prophylactic antimicrobials), and most recent chemotherapy regimen. Additionally, the clinician should question about sick contacts at home; updates on recent travel; daycare, school, and occupational exposures; animal exposures (e.g., new domestic pets such as cats or birds and farm animals); and dietary exposures (e.g., unpasteurized cheeses). On physical examination, specific attention should be focused on areas sometimes overlooked, such as the nasal passages and oropharynx, middle ears, genitalia, perineum (in particular, the perianal area), and scalp. Central venous line exit sites also are important areas for inspection.

INITIAL DIAGNOSTIC EVALUATION

Regardless of the risk designation of a pediatric patient presenting with fever and neutropenia, an infectious diagnostic evaluation is warranted in all such patients. Various testing modalities may be employed depending on the status of the patient. In all patients, routine blood cultures should be performed before initiation of antibiotics. Because most patients have central venous access, this would include culturing samples from all lumens of the central venous catheter.

Performing a peripheral blood culture in addition to central venous cultures is controversial. Multiple studies of paired cultures taken from pediatric and adult patients with underlying malignancy suggest a small but consistent probability of detecting true bacteremia from the peripheral culture when the central culture is negative.[1,22,35,104,116] A recent meta-analysis determined that 13 percent of bacteremias were identified only with a peripheral culture.[109] These data suggest that a peripheral blood collection should be considered concurrent with cultures from the central line.

Although no pediatric or adult study has documented the yield of daily blood cultures in an otherwise clinically stable patient with persistent fever and neutropenia, it is unlikely that continued daily cultures will identify a true pathogen if initial cultures were negative and the child is

clinically stable. Therefore, it is reasonable to follow the adult guideline recommendations, which suggest daily blood cultures for only the first 3 days of fever and neutropenia.[47] Repeat blood cultures are appropriate in patients with a significant clinical change (e.g., hypotension, tachypnea) or in those whose fever initially resolved but then recurred.

A urine culture is warranted if the patient presents with signs or symptoms of a urinary tract infection (UTI). The importance of routine urine cultures for children presenting with fever and neutropenia without signs or symptoms of a UTI is controversial. In a typical pediatric population, UTI is a common source of FUO.[23] Asymptomatic UTIs are likely to be more common in neutropenic children given the lack of an appropriate inflammatory response. This is evidenced by the fact that only 4 percent of oncology patients with a urine culture consistent with a UTI pathogen will have pyuria on urinalysis.[67]

Of the various observational trials that have prospectively evaluated patients with fever and neutropenia,[21,54,75,100] only two have commented on the impact of UTI. Hakim and colleagues[54] noted that of 337 patients presenting with fever and neutropenia, two (0.6%) had a positive urine culture. Urine culture was not a component of the routine diagnostic evaluation, and it is possible that there were more patients with a UTI as 53 percent of the cohort did not have an identified source of fever. Data from Santolaya and associates suggest that UTIs are more common, as they identified a urinary pathogen in 4.6 percent of fever and neutropenia episodes.[114] Again, urine culture was not performed as a routine diagnostic test so 4.6 percent may also be an underestimate of the true frequency of UTI in the setting of fever and neutropenia.

Given these data, routine urinalysis and urine culture in patients presenting with fever and neutropenia should be obtained if a midstream or clean catch specimen is feasible. In patients who require urinary catheterization for specimen collection, the risks of the intervention should be weighed against the benefit of potentially identifying the source of the fever. However, antibiotic administration should never be delayed if a patient is unable to provide a timely urine specimen.

In children with focal respiratory signs (e.g., tachypnea or auscultatory changes) or symptoms (e.g., cough or increased work of breathing) chest radiography should be a component of the initial diagnostic workup. Additionally, in children who are capable of producing an adequate sputum sample, one should be collected and sent for routine culture. The utility of routine chest radiography has been examined in children presenting with fever and neutropenia. Together, these studies evaluated 487 episodes of pediatric fever and neutropenia; only five chest radiographs revealed pneumonia in the absence of any respiratory signs or symptoms.[43,65,70,108] These data do not support the routine use of chest radiography in children with fever and neutropenia in the absence of respiratory symptomatology.

Finally, important findings noted on history or physical examination should dictate additional testing for less common sources of infection. For example, a patient with fever and neutropenia and a reported history of a lovebird in the home should prompt additional testing for cryptococcosis early in the evaluation period.[133] Likewise, identification of black cutaneous lesion(s) in a patient with antecedent neutropenia should prompt consideration for immediate biopsy over concern for a cutaneous mold infection. In the setting of exotic exposures or important clinical findings, consultation with an infectious disease physician with experience in immunocompromised patients may be warranted early in the hospitalization, because early identification of less common opportunistic infections will likely translate into improved patient care.

INITIAL THERAPY FOR FEVER AND NEUTROPENIA

Traditionally, the standard of care for fever and neutropenia has been hospital admission with administration of intravenous broad-spectrum antibiotics. However, employing a risk stratification rule offers the opportunity to differentially manage children at low and high risk for infectious outcomes. Children at high risk should be admitted for initiation of a parenteral antibiotic regimen with broad-spectrum gram-negative coverage, including *P. aeruginosa* and reasonable gram-positive coverage for organisms such as the viridans group streptococci. Antibiotic options that meet these criteria include an antipseudomonal penicillin (e.g., piperacillin-tazobactam), a cephalosporin (e.g., cefepime), or a carbapenem (e.g., meropenem or imipenem-cilastatin). Two separate pediatric meta-analyses compared antipseudomonal penicillins to cephalosporins[81] and antipseudomonal penicillins to carbapenems[82] and concluded similar effectiveness of each of these options for empirical therapy.

It is important to note that a meta-analysis of predominantly adult randomized controlled trials identified a significant increased risk for all-cause mortality in patients receiving cefepime in contrast to those receiving other β-lactam agents for fever and neutropenia.[94,142] However, in a subsequent analysis, the U.S. Food and Drug Administration (FDA) supplemented the available published data with unpublished mortality data specific to febrile neutropenic patients and found no mortality difference among the antibiotic options. The FDA specifically reviewed the available case report forms from the fever and neutropenia trials and could not identify a biologically plausible reason for the previously identified association of cefepime and death.[66] An additional meta-analysis of fever and neutropenia trials and a retrospective investigation of pediatric AML patients did not reveal a difference in mortality risk between those exposed to cefepime in contrast to other antibiotics commonly used for fever and neutropenia.[44,132] Based on evaluation of the available data, cefepime should remain a viable option for empirical therapy for febrile neutropenia.

Because gram-positive organisms are an increasing cause of fever and neutropenia episodes, the utility of adding additional broad gram-positive coverage (e.g., vancomycin) to the empirical regimen has been questioned.

Although pediatric-specific data do not exist, multiple adult randomized controlled trials have investigated the efficacy of adding a glycopeptide to various β-lactam–containing regimens. These trials were summarized in two separate meta-analyses, each of which failed to identify a significant benefit relative to all-cause mortality in patients receiving empirical glycopeptide therapy.[93,136] Therefore, routine empirical glycopeptides are not recommended for fever and neutropenia.

In general, for a child presenting with fever and neutropenia who is otherwise stable, monotherapy with an antipseudomonal penicillin, an antipseudomonal fourth-generation cephalosporin, or an antipseudomonal carbapenem is appropriate. There is a paucity of published data that report on the importance of certain patient-level factors in determining an appropriate antibiotic regimen. However, as suggested by the adult fever and neutropenia guidelines,[47] certain patient specific factors should be evaluated when managing antibiotic regimens. For instance, in patients with or developing hemodynamic instability, the addition of a second gram-negative agent (e.g., an aminoglycoside) and broader gram-positive therapy (e.g., vancomycin) may be necessary. Additionally, broad gram-positive therapy should be considered in patients with evidence of a focal gram-positive infection (e.g., cellulitis or central access tunnel infection). Finally, a history of an invasive infection with a resistant organism (e.g., methicillin-resistant *S. aureus*) should inform empirical antibiotic choices during subsequent fever and neutropenia episodes. Likewise, each institution's choice of empirical therapy should be guided by local active surveillance of the resistance profiles of pathogens identified among oncology unit patients. In certain institutions, an identified change in the resistance profiles may warrant a switch from one antimicrobial agent to another or from empirical monotherapy to empirical multiagent therapy.

For low-risk patients, outpatient management with either oral or parenteral therapy for fever and neutropenia has garnered much support in recent years. Some pediatric-specific randomized trials have noted similar safety for early hospital discharge on intravenous therapy versus continued hospitalization,[3,112] early hospital discharge on oral therapy versus continued hospitalization,[17] inpatient intravenous versus inpatient oral therapy,[19] and outpatient intravenous versus outpatient oral therapy.[53,90,92,95] Although each of these studies was limited by small sample sizes, a pediatric stratified analysis of randomized trials and a pediatric-specific meta-analysis of prospective studies support the safety of outpatient management and oral antibiotic administration in low-risk children with fever and neutropenia.[83,130] In addition, outpatient management of low-risk febrile neutropenic patients is associated with a large reduction in health care costs in contrast to inpatient management.[112,129] Of interest, although patients and parents both report that the home environment has a positive impact on physical activity, self-esteem, and family activities,[123] it seems that some parents may prefer inpatient management for fever and neutropenia episodes given the perception of reduced effectiveness of outpatient management.[17,36,103] As the standard of care for low-risk fever and neutropenia transitions from the inpatient to outpatient setting, additional clinical efforts will be necessary to support families and evaluate the effectiveness of these approaches outside of carefully monitored clinical trials.

DIAGNOSTIC EVALUATION FOR PERSISTENT FEVER AND NEUTROPENIA

A primary concern in the patient with prolonged fever and neutropenia (>96 hours) despite broad-spectrum antibiotics is the possibility of an invasive fungal infection, especially in patients considered to be at high risk for it. No specific clinical signs suggest an invasive fungal infection diagnosis, and routine cultures have limited yield for yeasts such as *Candida* spp. and extremely poor yield for molds such as *Aspergillus* spp.[10] Thus, focus has increased on improving diagnostic modalities for detecting invasive fungal infection in these patients. Two serum fungal biomarkers have received significant attention, galactomannan and β-D-glucan. Galactomannan, developed to detect a cell wall component of *Aspergillus* spp., has been well evaluated in pediatric cohorts. Table 68-3 displays the operating characteristics of these pediatric studies.* The data suggest that galactomannan testing can be useful in identifying patients with actual invasive aspergillosis. Of importance, the false positive rate of the assay has improved with recent analyses.

The appeal of β-D-glucan is that it has the potential to detect a wide variety of invasive fungi, with the exception of *Cryptococcus* and molds of the Mucorales order.[85] Large adult prospective trials describing the operating characteristics of β-D-glucan have been compelling[41,91] and a positive β-D-glucan result is considered as supportive evidence for probable invasive fungal infection according to the most recent European Organization for Research and Treatment of Cancer/Invasive Fungal Infections Cooperative Group and the National Institute of Allergy and Infectious Diseases Mycoses Study Group (EORTC/MSG) Consensus Group definitions for invasive fungal infection.[32] However, to date, data on the β-D-glucan assay in children have been limited to a cohort of healthy patients[122] and a smaller number of immunocompromised children and thus it should not be used clinically in children with fever and neutropenia until additional studies are performed.[88,144]

PCR testing represents a third novel approach to detect an invasive fungal infection. A pan-fungal PCR approach has been evaluated in both pediatric[40] and adult patients[61] with neutropenia with and without fever. The operating characteristics of this technique were reasonable but did not prove to be better than galactomannan testing. PCR testing has promise but this approach is limited by the need for release of DNA outside of the fungal cell wall and the potential for sample contamination.[10]

Lastly, radiographic testing such as systematic computed tomography (CT) imaging has been proposed as a

Modified from Fisher BT, Zaoutis TE, Park JR, et al. Galactomannan antigen testing for diagnosis of invasive aspergillosis in pediatric hematology patients. *J Pediatr Infect Dis Soc* 2012;**1**:109.
* The definition of proven or probable aspergillosis varied depending on the publication.
†Defined as the number of false-positive results per total number of episodes/patients without invasive aspergillosis.
‡Case-control study design may inflate the calculated false-positive rate for this study.
§After accounting for piperacillin-tazobactam exposure the false-positive rate was 8.5%.
¶All three probable cases required inclusion of positive galactomannan enzyme immunoassay results to qualify for this designation
FN, False-negative; *FP,* false-positive; *TN,* true-negative; *TP,* true-positive.

method to detect an infectious etiology of persistent fever and neutropenia. Evaluation of adult patients early in the course of prolonged fever and neutropenia suggests that high-resolution CT scan of the chest with subsequent diagnostic intervention (e.g., bronchoalveolar lavage) has the potential to direct additional specific antimicrobial therapy[57] and to reduce the time to diagnosis of invasive pulmonary aspergillosis.[20] Pediatric data on the utility of systematic CT imaging of the sinuses, chest, abdomen, and pelvis in prolonged fever and neutropenia are limited to a retrospective case series of 68 pediatric episodes. In just two of the cases, chest CT scan results altered the course of therapy.[2]

Of the previously mentioned diagnostic tests, only the data on galactomannan testing support its use as an adjunctive diagnostic tool in the setting of pediatric prolonged fever and neutropenia. Nonetheless, additional investigation is necessary to better define the ideal galactomannan testing approach. Regardless of the diagnostic modality, the challenge with interpreting the data on these adjunctive tools in the setting of prolonged fever and neutropenia is that in previous studies significant variation existed relative to patient populations, interpretations of positive assay threshold, type of test used, timing and frequency of testing, and definitions for invasive fungal infection. It appears that no single diagnostic modality has proven ideal for directing the care of the pediatric patient with prolonged fever and neutropenia. It may be that a combination of diagnostic tests is necessary to best inform clinical practices. In a randomized, controlled trial in adults, a preemptive antifungal therapy approach guided by clinical assessment, laboratory testing (e.g., galactomannan testing), and chest imaging results was shown to be as effective as empirical antifungal therapy.[27] Future studies are necessary to confirm this as an appropriate approach for prolonged fever and neutropenia in children.

THERAPEUTIC ADJUSTMENTS FOR PROLONGED FEVER AND NEUTROPENIA

Adjustment of Empirical Antibiotic Therapy

Few data exist to guide recommendations for adjusting antibiotic therapy in patients with prolonged fever and neutropenia with or without an identified source. One randomized, controlled trial in adults found that the addition of vancomycin in patients with persistent fever and neutropenia receiving piperacillin-tazobactam monotherapy failed to provide benefit relative to fever resolution.[26] Guidelines for both adult and pediatric patients agree that the persistence of fever alone is not an indication for expanding or modifying antibiotic coverage, assuming the patient remains clinically stable. In this setting, close monitoring is necessary to evaluate for changes in clinical status.[47,76] Signs of clinical deterioration, for example, hypotension or respiratory distress, should prompt expansion of the antimicrobial regimen. The nature of the clinical change should dictate the specific addition or modification to the antimicrobial regimen.

An important question is the optimal time to discontinue antibiotics when fever has resolved but neutropenia persists. Retrospective[8,9,63,74] and prospective observational[25,89] and randomized[113] studies support the safety of antibiotic cessation after fever resolution with evidence of bone marrow recovery. It also may be safe to stop antibiotics irrespective of bone marrow recovery on day 3 in low-risk patients.[113] However, the optimal approach in high-risk patients without bone marrow recovery is less clear. Pizzo and colleagues[101] showed that if empirical antibiotics are stopped at 7 days in patients with

resolution of fever but persistent neutropenia, a significant risk exists for return of fever and potential for death. Future research is necessary to better define the appropriate timing for antibiotic cessation in high-risk children with persistent neutropenia.

In patients in whom an organism is thought to be the source of fever, the antimicrobial regimen should be modified to target the identified organism. It is not clear whether it is necessary to retain the same broad-spectrum coverage appropriate for initial presentation of high-risk fever and neutropenia or whether it is possible to focus the antibiotic regimen while the patient is still neutropenic. A reasonable approach would be to maintain broad-spectrum coverage if empirical therapy would otherwise be continued and to narrow therapy if criteria for cessation of empirical therapy are met. Future investigation of narrowing therapy in high-risk patients with an identified pathogen is necessary to determine whether this approach is safe.

Initiation of Antifungal Therapy

Initial prospective randomized data highlighted the success of empirical antifungal therapy in children with persistent fever and neutropenia despite broad-spectrum antibiotics.[100] As previously discussed, considerable attention has since focused on defining patients at high risk for invasive fungal infection. Current guidelines for adults support the initiation of empirical antimold therapy in patients with persistent or recurrent fever lasting 4 to 7 days when the duration of neutropenia is anticipated to persist beyond 7 days.[47] Recently published pediatric-specific guidelines have supported the initiation of empirical antifungal therapy in patients at high risk for invasive fungal infection after 96 hours of fever and neutropenia that is not responsive to broad-spectrum antibiotics when the duration of neutropenia is anticipated to last longer than 10 days.[75] In patients at low risk for invasive fungal infection it is reasonable to withhold empirical antimold therapy.

When initiating an empirical antimold agent, options include an amphotericin product (amphotericin B deoxycholate, lipid amphotericin, or liposomal amphotericin), an echinocandin (anidulafungin, caspofungin, or micafungin), or an azole (voriconazole or posaconazole). Pediatric prospective randomized trials have compared caspofungin to liposomal amphotericin[80] and the latter to amphotericin B deoxycholate.[102] Although similar relative to efficacy outcomes, significantly fewer side effects were associated with liposomal amphotericin in contrast to amphotericin B deoxycholate. Safety and efficacy comparisons showed no difference between caspofungin and liposomal amphotericin. Given these data, caspofungin or liposomal amphotericin are both appropriate first-line agents for empirical antifungal therapy. Second-generation triazoles represent alternative options for empirical mold therapy; however, the lack of pediatric-specific data for these agents limits the feasibility of their use. Although voriconazole dosing recommendations are available for children 2 years of age and older, the optimal dosing regimen has not yet been defined and intrapatient and interpatient variability in voriconazole pharmacokinetics among the pediatric population is significant.[64,118] Dosing recommendations for posaconazole do not exist for those younger than 13 years of age. Finally, neither voriconazole nor posaconazole have been specifically studied as an empirical antimold therapeutic agent in children.

The empirical antifungal approach for prolonged fever and neutropenia has been challenged because of the lack of specificity of prolonged fever and neutropenia as a marker for invasive fungal infection, the potential to unnecessarily expose patients to antifungal agents who do not have an invasive fungal infection, and the increased cost in administering these agents for prolonged periods.[33,84] Although designation of high- and low-risk invasive fungal infection status has reduced some unnecessary empirical therapy, it has not eliminated it. As noted previously, an alternative approach to empirical antifungal therapy is a preemptive strategy. In this approach, the results of a combination of diagnostic studies (e.g., fungal biomarkers and CT scans) are used to inform the initiation of antifungal therapy. In a randomized trial of high-risk adult patients with fever and neutropenia, Cordonnier and colleagues[27] showed that a preemptive approach reduced the cost associated with antifungal use without a change in mortality. However, the preemptive approach was associated with a higher rate of invasive fungal infection. Further refinement of a preemptive approach with a focus on pediatric cohorts is necessary before such a strategy can be adopted in children.

The appropriate time to discontinue empirical antifungal therapy has not been well defined. A conservative approach is to continue until resolution of neutropenia; this approach is supported by a recently published pediatric guideline.[76] Some clinicians perform CT scans at the time of neutropenia resolution and use this information to inform cessation of antifungal therapy. However, no data exist to document the clinical impact of this approach. Future research should focus on identifying the optimal criteria for cessation of antifungal treatment in the empirical setting.

PREVENTION MEASURES

Antibacterial Prophylaxis

Much effort has focused on determining the efficacy and safety of antibacterial prophylaxis in patients with cancer. In 2005, two large, randomized, placebo-controlled trials evaluated the efficacy of levofloxacin for preventing fever in patients with anticipated short and long periods of neutropenia.[18,30] These trials discovered that levofloxacin prophylaxis reduced the rates of fever and bacteremia during periods of anticipated prolonged neutropenia[18] and similarly reduced the rate of fever and infection during anticipated short periods of neutropenia.[30] Further, a meta-analysis of 95 randomized trials revealed a significant reduction in mortality when antibiotic prophylaxis was administered to neutropenic patients.[48] Based on these data, multiple guidelines for adults support the use of fluoroquinolone prophylaxis.[47,73] However, the limited pediatric data regarding the utility of antibacterial

prophylaxis[4] has precluded a similar pediatric recommendation. Furthermore, potential negative consequences associated with prophylaxis, such as an increase in resistance among colonizing organisms, or precipitation of *Clostridium difficile* infection, were not adequately evaluated in the aforementioned large trials in adults. Currently, the Children's Oncology Group is conducting a trial to investigate the benefits of levofloxacin prophylaxis in high-risk children with neutropenia and intends to evaluate some of these important secondary outcomes.

Antifungal Prophylaxis

Prophylactic antifungal therapy also has been explored as a mechanism to reduce invasive fungal infection in patients with neutropenia. The earliest trials in adults showed fluconazole was efficacious in contrast to placebo in reducing systemic and superficial fungal infections in bone marrow transplant recipients.[50,121] A subsequent meta-analysis suggested that the benefit of prophylactic fluconazole was realized in the setting of increased risk (>15%) for systemic fungal infection.[62] This meta-analysis appropriately highlighted the need to consider the prevalence of invasive fungal infection when considering the impact of antifungal prophylaxis in a specific patient population. More recently, agents with antimold activity have been evaluated in the prophylactic setting. Vehreschild and colleagues[137] showed, in a small cohort of adult AML patients, that voriconazole in contrast to placebo was efficacious in reducing the rate of pulmonary infiltrates.[137] In additional clinical trials involving predominately adults, fluconazole has been compared to posaconazole in patients with prolonged neutropenia,[28] to voriconazole in allogeneic stem cell transplant recipients,[140] and to micafungin in stem cell transplant recipients.[135] The former study revealed that posaconazole was efficacious at reducing invasive aspergillosis, whereas the latter studies suggested that voriconazole and micafungin prophylaxis trended toward improved protection against invasive aspergillosis in contrast to fluconazole. Collectively, these data support guideline recommendations in adults to administer antifungal prophylaxis in patients considered at high risk for invasive fungal infection. However, the guidelines for adults were not consistent as to when to administer fluconazole and when to escalate to antimold prophylaxis.[47,73]

Pediatric-specific data for antifungal prophylaxis from randomized clinical trials are not available. Based on the available data in adults, most pediatric experts would support the initiation of fluconazole prophylaxis in patients at high risk for invasive fungal infection.[38] The benefits of broadening prophylaxis to include antimold coverage in a pediatric population are not yet well defined. Currently, a randomized trial sponsored by the Children's Oncology Group is actively enrolling patients to compare the efficacy of caspofungin to fluconazole prophylaxis in pediatric patients with AML. The outcome of this study should inform the importance of antimold activity in a fungal prophylaxis regimen for high-risk pediatric patients.

Hospital Infection Control Practices

Children receiving chemotherapy represent a patient population at high risk for hospital-acquired infection (HAI) because they often require prolonged hospital admissions during which they are immunosuppressed. Recently, McCullers and colleagues[86] documented the impact of HAIs at a single institution. Not unexpectedly depth (<100/mm^3) and duration of neutropenia, as well as prolonged length of stay were identified as risk factors for HAI. Over the 26-year study period they documented a decrease in the rate of HAIs that correlated with the implementation of various infection control initiatives.

These data strongly support the potential impact of infection control practices in reducing HAI even in high-risk patient populations. Important infection control practices often focus on interrupting the transmission of infectious pathogens from health care workers to their patients. Such practices include programs to promote high compliance of hand hygiene, enforcement of work restriction at times of health care worker illness, and optimization of health care worker influenza vaccination.[16,42,119] Enacting a mandatory vaccination policy has proved to result in near complete health care worker vaccine coverage at a large children's hospital.[42] Finally, use of a protocol to screen visitors before entering the patient room can reduce unnecessary patient exposures.

Despite the importance of infection control practices, significant variation likely exists in policies across institutions and in enforcement of policies within institutions. Future efforts are needed to establish goals for reducing HAIs and guidelines for standardized infection control practices specific to pediatric oncology patients to achieve these goals. Ultimately, the institution of any standardized infection control practice should be accompanied by an institutional-level surveillance of HAIs to monitor the effectiveness of each intervention.

CHAPTER 69

Opportunistic Infections in Hematopoietic Stem Cell Transplantation

Christopher C. Dvorak • William J. Steinbach

Advances in supportive care have led to considerable improvements in hematopoietic stem cell transplant (HSCT) outcomes over the last decade. The 1-year transplant-related mortality rate for children with acute leukemia and unrelated donor HSCT performed before 1995 approached 40 percent. More recently, rates from 2003 to 2006 fell by more than half to approximately 15 percent.[106] This has led to significantly more alternative donor HSCTs performed for a wide variety of nonmalignant diseases, including T-cell and phagocyte primary immunodeficiencies, hemoglobinopathies, bone marrow failure syndromes, and metabolic syndromes. However, these children often have relatively intact immune systems at the time of HSCT and thus require increased pre-HSCT immunoablation to prevent graft rejection. This often leads to delays in post-HSCT immune reconstitution, which in turn is associated with significant opportunistic infections. In addition to causing significant morbidity and prolonged hospitalizations, opportunistic infections cause a staggering 37 to 40 percent of transplant-related mortality following allogeneic HSCT.[135]

Evidence indicates that certain opportunistic infections may play a role in the triggering of alloreactivity and graft-versus-host disease (GVHD). For example, animal models suggest that administration of probiotics may alter the intestinal microflora and decrease inflammation in mesenteric lymph nodes, thereby abrogating GVHD.[59] A randomized trial of fluconazole versus placebo demonstrated less severe GVHD of the intestinal tract in the fluconazole recipients, possibly as a result of decreased intestinal antigenic stimulation.[111] Some data suggest that both cytomegalovirus (CMV) and human herpesvirus–6 (HHV-6) reactivations can trigger the development of GVHD.[105,141] Because GVHD is another significant component of transplant-related mortality after allogeneic HSCT, further understanding of the interplay between opportunistic infections and initiation of GVHD may provide another avenue toward making HSCT a safer procedure with improved overall outcomes.

EPIDEMIOLOGY

Although opportunistic infections do occur after autologous HSCT, the much more profound and ongoing

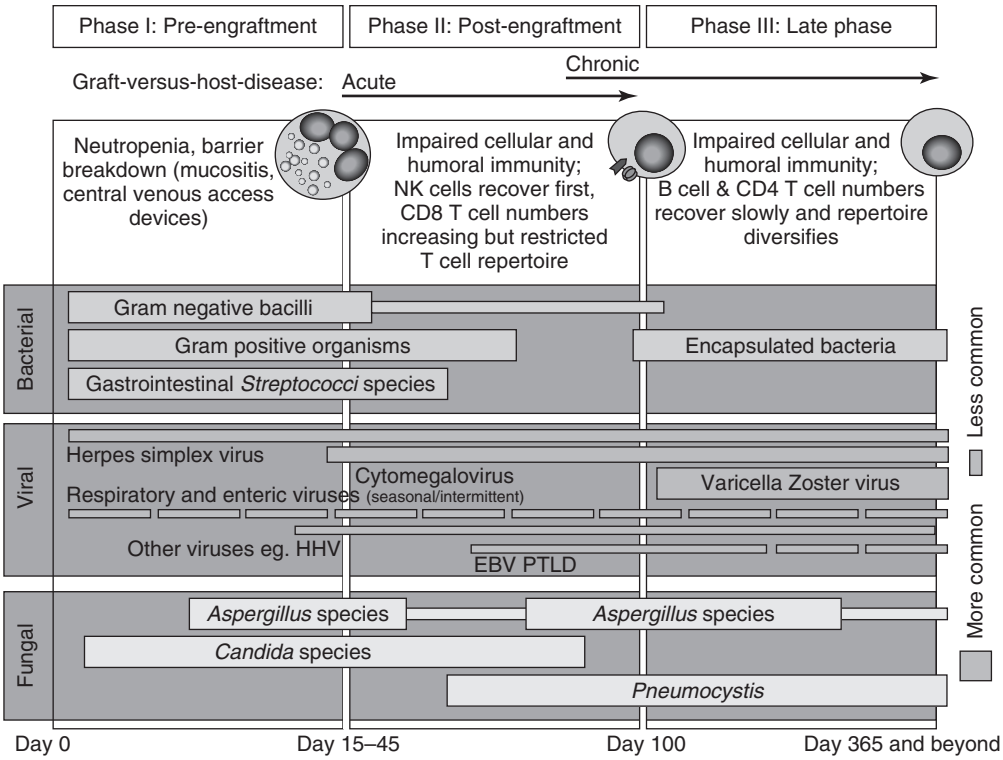

FIGURE 69-1 ■ The phases of opportunistic infections after allogeneic HSCT. *EBV,* Epstein-Barr virus; *HHV,* human herpesvirus; *NK,* natural killer; *PTLD,* posttransplant lymphoproliferative disease. (From Tomblyn M, Chiller T, Einsele H, et al. Guidelines for preventing infectious complications among hematopoietic cell transplantation recipients: a global perspective. *Biol Blood Marrow Transplant* 2009;**15**:1143–238. Used with permission from the publisher.)

T-cell dysfunction that occurs before and after allogeneic HSCT makes opportunistic infections far more likely to occur in this population. Multiple therapy-induced alterations of host defenses contribute to this risk.[99] The three major contributors to the development of an opportunistic infection are (1) breakdown in natural barriers (e.g., indwelling central venous catheters and mucositis), (2) defects in cell-mediated immunity (e.g., lymphopenia from corticosteroids and other anti–T-cell cytotoxic agents), and (3) deficient numbers of phagocytes (e.g., as a result of myeloablative chemotherapy). Classically, three phases of risk for opportunistic infections occur after HSCT, as shown in Figure 69-1.[175]

Phase I: Pre-Engraftment (<30 Days)

Infections in phase I are similar to those seen with other forms of profoundly myelosuppressive chemotherapy, and include gram-positive and gram-negative bacteremia, candidemia, invasive aspergillosis, and reactivation of oral herpes simplex virus contributing to mucositis. Administration of granulocyte-colony stimulating factor (G-CSF) during this period will shorten the time to recovery of neutrophils by several days and may decrease rates of documented infections.[46] However, less evidence exists that G-CSF improves infection-related or transplant-related mortality, and it may increase the incidence of acute GVHD.[178] Therefore, only approximately 60 percent of HSCT centers use G-CSF routinely.[96]

Phase II: Early Post-Engraftment (30 to 100 Days)

Some infections in phase II are caused by a combination of persistent defects in the function of the patients' phagocytes (partly from the administration of corticosteroids to treat acute GVHD) and retention of central venous catheters, which can lead to gram-positive bacteremia and candidemia. Other infections are due to the ongoing relative and functional lymphopenia and involve reactivations of CMV and other double-stranded DNA (dsDNA) viruses, *Pneumocystis jiroveci*, or certain parasitic infections.

Phase III: Late Post-Engraftment

Infections in phase III are generally caused by ongoing immunosuppressive therapy for the treatment of chronic GVHD, which also is associated with functional asplenia. Thus, patients can develop infections with encapsulated bacteria, *P. jiroveci*, and ongoing problems with dsDNA viruses. There is also a second important peak of invasive aspergillosis during this time.

Knowledge of the timing of the variety of infections that can occur after HSCT allows clinicians to develop rational approaches to antimicrobial prophylaxis, diagnostic monitoring for infections, and earlier treatment of proved infections.

MAJOR TYPES OF OPPORTUNISTIC INFECTIONS AFTER HEMATOPOIETIC STEM CELL TRANSPLANTATION

Bacterial

Classic Gram-Positive and Gram-Negative Bacteria

Bacterial infections after HSCT most commonly divide into gram-positive organisms originating from the skin or gastrointestinal tract, and gram-negative organisms translocating from the gastrointestinal tract. The period of highest risk for bacterial bloodstream infections, especially with enteric gram-negative rods, is the pre-engraftment period,[27] during which the incidence of bacteremia can range from 21 to 34 percent and 21 to 58 percent for patients undergoing autologous and allogeneic HSCT, respectively, although some studies report no difference between the two groups.[24,25,28,29,126] In HSCT patients, bloodstream infections before engraftment are a significant independent predictor of mortality.[1,144] Several studies have demonstrated that either host or donor polymorphisms in genes responsible for immunity may contribute to the risk for bacterial infections.*

Given the significant risk for developing bacteremia, it is surprising that there is little evidence that routine antibacterial prophylaxis plays a role in pediatric HSCT recipients. In adult patients undergoing HSCT, general consensus exists regarding the utility of a prophylactic quinolone with antipseudomonal activity.[175] This derives from data generated by a large contemporary trial of levofloxacin prophylaxis in which 45 percent of enrolled patients were undergoing autologous HSCT. The rates of fever and bacteremia were significantly reduced in patients receiving levofloxacin, but prophylaxis did not have an impact on mortality.[22] Similar results have been reported using ciprofloxacin and vancomycin as a prophylactic regimen for autologous HSCT patients.[54] Unlike autologous HSCT, no contemporary large randomized trials of the use of antibiotic prophylaxis versus no prophylaxis in allogeneic HSCT patients have been conducted. Most existing studies in HSCT patients have included small patient numbers and have compared two prophylactic regimens, as opposed to prophylaxis versus no prophylaxis, and have given rise to variable results.[68,92,138,163,168] All of these studies were done in adult patients; therefore, caution must be used in applying the specific results to pediatric HSCT recipients.

Other approaches to antibacterial prophylaxis use nonsystemic treatments to potentially spare medication toxicities and the development of resistant organisms. Chlorhexidine gluconate is an antiseptic bactericidal to gram-positive and gram-negative bacteria, including multidrug resistant organisms. The mechanism of action involves bacterial membrane disruption; its onset is relatively rapid, and the effect is persistent. A 2 percent chlorhexidine gluconate–impregnated cloth product has been studied as a skin cleansing product in the adult critical care setting, where it has been shown to decrease risk for central line–associated infections by at least 50 percent and new acquisition of multidrug-resistant organisms by 30 to 50 percent.[14,40,142,189] Currently, no peer-reviewed published studies report on the effect of chlorhexidine gluconate bathing on prophylaxis of bloodstream infections in children undergoing HSCT. Similarly, because many cases of bacteremia are seen in the setting of central venous catheters, the use of ethanol lock solutions may potentially decrease central venous catheter colonization without the concern of resistance from antibiotic locks. A randomized, double-blind study in adults receiving chemotherapy or HSCT demonstrated the benefit of ethanol locks versus heparin.[154] Studies of prophylactic ethanol locks in pediatric HSCT recipients are currently lacking.

When patients develop a fever early after transplant, empirical antibacterial treatment is usually started. Although a variety of different regimens exist, they are generally tailored to cover *Streptococcus* spp. and *Staphylococcus* spp., plus enteric gram-negative organisms, based on local susceptibility patterns.

Clostridium difficile

Although hardly unique to the pediatric HSCT population, because of the widespread use of broad-spectrum antibiotics for empirical therapy of febrile neutropenia *Clostridium difficile* associated diarrhea is not uncommon. In adults, up to 15 percent of patients may develop this complication within 30 days of HSCT,[3] although pediatric-specific data are relatively lacking. Prevention of *C. difficile* may potentially be accomplished through the administration of certain strains of probiotics.[117] It is not yet clear that this practice is safe in the immediate post-HSCT phase, during which a combination of neutropenia and compromised intestinal integrity could theoretically lead to the development of bacteremia from the ingested strain.[70] Treatment of *C. difficile*–associated diarrhea in the pediatric HSCT patient is similar to that of the general population, with metronidazole or oral vancomycin, although caution must be used during the conditioning phase of HSCT when metronidazole can enhance toxicities from radiation or busulfan.[67]

Encapsulated Organisms

Patients with chronic GVHD appear to have defects in their splenic function, and thus encapsulated bacteria, such as *Streptococcus pneumoniae*, have been noted to cause significant mortality. Prophylaxis with penicillin appears to diminish this risk,[93] although the optimal duration of treatment is not yet defined. In patients with chronic GVHD, serum immunoglobulin (Ig)G levels should be monitored and, for patients with levels less than 400 mg/dL, administration of intravenous gammaglobulin should be considered.[175]

Mycobacteria

Although less common than invasive fungal infections, infections with mycobacteria must always be considered in the differential diagnosis of pulmonary nodules after

*References 7, 35, 95, 119, 150, 186.

HSCT. In developed countries, classic *Mycobacterium tuberculosis* infections are very rare in children undergoing HSCT, although it always should be considered in patients whose households have recently immigrated.[58] More commonly encountered are environmental atypical nontuberculous mycobacteria (NTM), which can cause infections in the lungs, skin, lymph nodes, and bloodstream. Because of the relative rarity of NTM infections, a general paucity of literature exists in the HSCT population. NTM infections have been reported to occur in as many as 9.7 percent of T-cell depleted and 7 percent of conventional allogeneic HSCTs in adults, although the mortality rate was low.[193] Pediatric HSCT recipients have a somewhat lower rate of NTM infections (3.8%), which occur at a median of 115 days (range, 14 to 269 days) after HSCT.[181]

The exact risk factors associated with the development of NTM infections after allogeneic HSCT are not well characterized. The protective immunity against NTM infections appears to be primarily driven by interferon (IFN)-γ production by T-cells, as evidenced by the high rate of NTM infections in patients with IFN-γ deficiency.[72] Thus, T-cell depletion (ex vivo or with T-cell–depleting antibodies) or treatment of GVHD with immunosuppressants that block IFN-γ might be expected to be risk factors for the development of NTM infections. Similarly, patients with an underlying T-cell immunodeficiency might be colonized with an NTM organism pre-HSCT that puts them at risk for developing NTM disease after HSCT. The optimal treatment of NTM infections is not clear. A wide variety of traditional antibiotics and antituberculosis agents have some activity against NTM organisms, but reports vary on the number of agents that must be used in combination and the duration of optimal therapy. In patients with human immunodeficiency virus (HIV) infection, the general recommendation is to treat most cases of NTM infections for 12 months after establishment of negative cultures.[66] It is not clear that such a prolonged duration is required for HSCT patients who, in the absence of chronic GVHD, tend to have improvement in, and even normalization of, their T-cell function over time.

Fungal

Although bacteria represent the most common infection after HSCT, invasive fungal infections account for a significant amount of posttransplant mortality. Several retrospective reports on the development of invasive fungal infections in pediatric HSCT patients have been published, with a 1-year incidence as high as 13 to 20 percent and a 58 to 83 percent mortality.[12,49,79,152] The most commonly identified invasive fungal organisms after HSCT are *Candida* and *Aspergillus* spp. Patients who are considered to be at the highest risk for developing an invasive fungal infection after HSCT are those who undergo transplant from either an unrelated donor (including umbilical cord blood) or a partially matched related donor or for treatment of a malignancy, bone marrow failure syndrome, or congenital immunodeficiency.*

Currently, use of antifungal prophylaxis is nearly universal in HSCT patients. Empirical therapy directed against resistant *Candida* or molds generally commences after approximately 72 hours of prolonged fevers despite administration of broad-spectrum antibacterials. One surprising feature to note from the original prophylactic fluconazole studies is that, even in the placebo arm, more than 80 percent of HSCT patients did not develop an invasive fungal infection, although these studies did include lower-risk autologous HSCT recipients.[63,164] This suggests that other explanations must exist for the development of invasive fungal infection after HSCT. Researchers are now finding that either host or donor polymorphisms in genes responsible for immunity appear to play a significant role in invasive fungal infections risk.* Most of these proposed genetic risk factors still require validation in a prospective multicenter cohort, but the future possibility of having different prophylactic strategies based on an a priori risk for developing an invasive fungal infection is promising.

Candida

Invasive candidiasis tends to occur during the neutropenic period immediately after HSCT, although later cases can occur in the setting of GVHD and prolonged immunosuppression, especially when central venous catheters are still in place. Typically, invasive candidiasis originates from endogenous *Candida* spp. colonizing patients' gastrointestinal tracts.[42] Pediatric patients appear to have relatively more invasive infections caused by *Candida parapsilosis* and fewer infections caused by *Candida glabrata*, in contrast to adults.[107] Two placebo-controlled trials from the early 1990s, performed in patients older than 12 years of age undergoing autologous or allogeneic HSCT, demonstrated that prophylactic administration of fluconazole significantly decreased invasive fungal infections.[63,163] Long-term follow-up of allogeneic HSCT patients given fluconazole prophylaxis supports a survival benefit (mortality 20% in the fluconazole arm vs. 35% in the placebo arm; $p = .004$), postulated to be at least partly due to less severe GVHD of the gastrointestinal tract in the fluconazole recipients from decreased intestinal antigenic stimulation.[111] The classic duration of fluconazole prophylaxis administration is during the high-risk period until 75 days after HSCT.[110,111] Because fluconazole does not cover *Candida krusei* and has variable activity against *C. glabrata*, alternative agents should be considered for patients known to be colonized with these species. Reasonable options include extended-spectrum triazoles, echinocandins, and lipid-formulations of amphotericin B (LFAB), all of which also have some coverage of *Aspergillus* spp.

When patients develop invasive candidiasis after HSCT, the most common site of infection is the bloodstream. In addition to initiation of appropriate antifungal agents, the standard practice is to discontinue all central venous catheters in patients with candidemia.[145] Less common, but more perplexing, disseminated *Candida* infections of the liver, spleen, or lungs can often be blood

*References 23, 49, 91, 111, 122, 175.

culture negative and may require tissue biopsy to establish a diagnosis. Serum β-glucan levels will be very useful for identifying cases of possible invasive candidiasis once the assay has been optimized for use in children.[167] Furthermore, in patients with disseminated candidiasis, a formal ophthalmologic evaluation is recommended to rule out *Candida* endophthalmitis, which may require intravitreal injection of antifungal agents to preserve vision.[149] For treatment of cases of invasive candidiasis, especially those who develop on fluconazole prophylaxis, the echinocandins are a class of antifungal agents that target β-(1,3)-D-glucan synthase and interrupt biosynthesis of the glucan polymers that make up fungal cell walls. Because mammalian cells do not possess cell walls, echinocandin administration to human patients has generally resulted in limited toxicity. Echinocandins possess fungicidal activity against *Candida* spp.[5] In some settings, the echinocandins may be superior to fluconazole[147] or amphotericin B[125] for treatment of invasive candidiasis.

Aspergillus

In adult HSCT recipients, *Aspergillus* spp. have a bimodal distribution, with a first peak at a median of 16 days and the second at a median of 96 days after allogeneic HSCT.[183,184] This second peak may be less pronounced in children.[28] Invasive aspergillosis can be one of the most devastating infections to occur after allogeneic HSCT. In a multivariate analysis of risk factors for mortality among a modern cohort of pediatric patients with invasive aspergillosis, the major risk factor for death was the development of invasive aspergillosis after an allogeneic HSCT.[23] Although treatment options for invasive aspergillosis have increased in recent years, significant attention also has been paid to preventing invasive aspergillosis infections. Although fluconazole prophylaxis has been shown to reduce the risk for invasive fungal infection relative to placebo, fluconazole lacks activity against *Aspergillus* spp. Given this lack of antimold activity, several trials have compared fluconazole to mold-active agents in hope of decreasing rates of invasive aspergillosis. The first of these trials compared fluconazole to low-dose conventional deoxycholate amphotericin B (D-AMB).[197] However, D-AMB did not show improvement over fluconazole and resulted in a higher adverse event rate. Several trials, including one in children,[151] have evaluated the LFAB (often given only three times per week) for antifungal prophylaxis in HSCT and acute leukemia patients.[87,116,137] However, like D-AMB, LFAB has not been shown superior to fluconazole in overall success and typically demonstrates increased side effects.

Extended-spectrum triazoles such as itraconazole, voriconazole, and posaconazole do possess anti-*Aspergillus* activity[5]; however, clear limitations exist to each as a potential prophylactic agent. Several trials of itraconazole versus fluconazole have been performed, and a meta-analysis showed significantly less invasive fungal infection,[187] but because of its common gastrointestinal side effects, greater drug interactions, and poor tolerability,[110] itraconazole prophylaxis has generally been abandoned in children. The results of a multicenter, double-blinded trial showed that voriconazole was not superior to fluconazole in the prevention of invasive fungal infection, although the safety profile was similar.[194] Given voriconazole's broader spectrum of activity, this result was surprising but may have been due to an incomplete understanding of the complex pharmacokinetics of voriconazole. In adults and children over the age of 12 years, voriconazole has nonlinear pharmacokinetics with relatively well-established dosing regimens. Even in adults, however, recent studies have questioned standard dosing regimens and have proposed dosing based on serum drug levels,[134,166,177] although the optimal goal serum voriconazole level is still unclear. Part of this variability may be due to allelic polymorphisms of the gene encoding for cytochrome (CYP)2C19, which can result in an increase or decrease in voriconazole metabolism.[134] In children, the situation is further complicated by linear voriconazole kinetics, so that younger children may need significantly higher dosages of voriconazole.[57,85,128] Voriconazole also has significant drug interactions with commonly used agents in a pediatric HSCT population. Voriconazole is a substrate of CYP2CP (major), 2C19 (major), and 3A4 (minor) and an inhibitor of 2C9 (moderate), 2C19 (weak), and 3A4 (moderate).[44] Proton pump inhibitors increase voriconazole levels, while voriconazole increases serum levels and toxicity of corticosteroids, imatinib, and many other medications.[44] The approved voriconazole label reports that concomitant use of voriconazole can cause a 1.7- to 3-fold increase in cyclosporine or tacrolimus levels, and recommends that the dosing of cyclosporine be decreased by 50 percent and the dosing of tacrolimus be decreased by 66 percent of the normal dose. A recent study demonstrated that in a cohort of 27 adult HSCT patients receiving voriconazole, 100 percent of patients required multiple tacrolimus dose reductions to achieve a safe target level.[176] Furthermore, the use of voriconazole with sirolimus is officially contraindicated, and when its use has been reported, investigators have recommended dropping the levels of sirolimus to 90 percent of original dosing at the time of initiation of voriconazole.[113]

Posaconazole is a triazole with broad coverage of most fungi, including mucormycosis (previously called zygomycosis).[5] In a trial of adult patients with neutropenia, posaconazole prophylaxis was superior to fluconazole or itraconazole, but was also associated with an increased risk for serious adverse events.[43] In a trial of teenagers and adults receiving treatment for acute or chronic GVHD, posaconazole was superior to fluconazole at preventing breakthrough and death from invasive fungal infection, with similar rates of toxicity.[180] Unfortunately, this did not translate to improved overall survival. Factors limiting the use of posaconazole in children include the lack of pharmacokinetic data in children younger than 13 years of age, the current lack of an intravenous formulation (because these children typically have nausea, mucositis, and poor oral intake during the highest risk period), and unreliable absorption in the setting of limited oral intake. Finally, posaconazole shares many of the same enzymatic pathways, and therefore drug interactions, as voriconazole. Because of the CYP interactions, azole prophylaxis is generally started after the conditioning regimen is complete. For patients who enter the HSCT period being treated for a preexisting invasive fungal

infection, discontinuation of azoles 72 hours before the start of conditioning chemotherapy is often done to allow the CYP enzymes to return to baseline function, although some data suggest that fluconazole coadministration may actually help with cyclophosphamide metabolism and decrease toxicity.[183]

Echinocandins possess fungistatic activity against *Aspergillus* spp.[5] In a prophylactic antifungal trial, micafungin demonstrated reduced need for empirical antifungal therapy and an improved safety profile in contrast to fluconazole.[185] However, the number of pediatric subjects enrolled was small (n = 84), and a reduction in the incidence of proved or probable invasive fungal infection was not demonstrated. The lack of impact on invasive fungal infection may have been because the incidence of breakthrough invasive fungal infections in both groups was very low, likely as a result of the inclusion of low-risk patients (46% autologous HSCT recipients) and very few patients undergoing umbilical cord blood transplant (n = 30). Caspofungin has been shown to be at least equivalent to itraconazole in the setting of antifungal prophylaxis,[115] with few caspofungin-related adverse events,[39] although prospective trials in this population are lacking. The major disadvantages to widespread echinocandin use are cost and the lack of an oral formulation.

If prophylaxis fails, the typical locations where invasive aspergillosis develops after an allogeneic HSCT are the lungs and sinuses, with not uncommon seeding of the brain. It should be noted that children do not always display the classic radiographic findings seen in adults with invasive aspergillosis, such as the air crescent or halo signs,[23] and a high index of suspicion must be maintained. Much attention has been focused on developing noninvasive tests for diagnosing invasive aspergillosis. Galactomannan is a polysaccharide cell-wall component released by *Aspergillus* during growth. The Platelia EIA *Aspergillus* galactomannan assay was approved by the U.S. Food and Drug Administration in 2003 for use in adult patients.[140] Early large-scale clinical testing included few children, but available data suggest that detection values for adult patients can be extrapolated to children.[73,172] Serum β-D-glucan (found in all fungi except *Cryptococcus* spp. and mucormycosis) can be detected using an approved diagnostic serum assay and has been found to have high specificity and high positive predictive values for the detection of invasive fungal infection in adults.[132] However, data on the performance of this assay in children are limited.[167] Ultimately, obtaining cultures through bronchial alveolar washings or biopsy is the best way to be certain of what organism is being treated. Speciation of the *Aspergillus* is also important if polyene therapy is planned, because of the intrinsic resistance of *Aspergillus terreus* to amphotericin B.[47]

Based on a pivotal trial performed in teenagers and adults, voriconazole has become the standard therapy for patients with invasive aspergillosis.[75] Because of the high mortality rate of invasive aspergillosis in post-HSCT patients, there has been great enthusiasm for potentially synergistic combination therapies, such as with a triazole and an echinocandin.[108] If amenable to a surgical approach, strong consideration should be made for resection of cases of invasive aspergillosis, which has been shown to improve mortality if disease is precariously located near a major vessel.[23] During the neutropenic period in patients who develop invasive aspergillosis, transfusions of irradiated random donor granulocytes have been proposed as a method to improve outcomes, although conclusive proof that this laborious procedure is beneficial is lacking.[158] Finally, exciting work has demonstrated the importance of adaptive immunity to fighting invasive aspergillosis.[74] Based on this, work has been done on creating *Aspergillus*-specific T cells for use in adoptive immunotherapy. It has been demonstrated that a cohort of patients who developed invasive aspergillosis after haploidentical HSCT and who received *Aspergillus*-specific T cells had significantly better resolution of the infection than a similar cohort not given the specific T cells.[139]

Rare Fungi

Less frequently, infections occur with the agents of mucormycosis (*Mucor*, *Rhizopus*, and *Absidia* spp.), *Trichosporon* spp., *Fusarium* spp., and other saprophytic fungi.[109] For these rare fungi, the key is to obtain culture identification, by biopsy if necessary, so that the optimal antifungal agent may be initiated. Posaconazole is a triazole with broad coverage of most fungi, including mucormycoses,[5] and thus may be the optimal treatment for many of these organisms, despite all of the caveats mentioned earlier regarding this agent. Recent work has demonstrated that Mucorales-specific T cells are generated after an infection with these organisms and thus might be useful as a diagnostic marker,[143] but also suggesting that generation of similar cells for treatment of Mucorales infections one day may be possible.

Pneumocystis jiroveci

Previously referred to as *Pneumocystis carinii*, that term now refers only to pneumocystis that infects rodents and *Pneumocystis jiroveci* refers to the distinct species that infects humans. The abbreviation PCP (or PJP) is often used to refer to pneumocystis pneumonia. PCP reactivations or infections are generally thought to be preventable after HSCT with administration of classic prophylaxis with trimethoprim-sulfamethoxazole (TMP-SMX). However, in the setting of alternative prophylaxis agents or TMP-SMX noncompliance, episodes of PCP do still occur beginning about 2 months after HSCT and continuing through recovery of T-cell functional immunity. TMP acts by interference with the bacterial dihydrofolate reductase, inhibiting synthesis of tetrahydrofolic acid and thus nucleic acid synthesis. Because of concerns about bone marrow toxicity, TMP-SMX is often held for several weeks after HSCT until evidence of neutrophil recovery, although this practice has been challenged.[56] The necessary amount of TMP-SMX required to prevent PCP has not been well studied, and a variety of dosing regimens exist, with administration 2 or 3 days per week being the most common. Generally, TMP-SMX is continued for at least 6 months after an allogeneic HSCT, although this should be lengthened for patients receiving ongoing immunosuppressive therapy.[179] In addition to possible bone marrow suppression, many patients have allergic or other reactions to TMP-SMX that induce

clinicians to prematurely discontinue its use. However, the optimal second-line prophylactic agent is not well defined and all options appear to be potentially less effective than TMP-SMX. Options that have been used include oral dapsone, intravenous or inhaled pentamidine, and oral atovaquone. Dapsone is inexpensive but has a high incidence of adverse events, especially in patients with glucose-6-phosphate deficiency.[155] Intravenous pentamidine given every 4 weeks also has been used, although inadequate protection has been noted in children under 2 years of age and those undergoing HSCT,[89] who may need more frequent dosing. Aerosolized pentamidine is generally well-tolerated, other than occasional bronchospasm, but its effectiveness has been questioned.[188] Atovaquone is generally well-tolerated, but absorption can be limited in patients not eating diets containing fatty foods. In vitro, the echinocandin class of antifungal agents appear to have some activity against the cyst form of *P. jiroveci*. To date, no studies have evaluated the use of echinocandins as a solitary prophylaxis agent; however, a few case reports have described its potential utility in combination with TMP-SMX for the treatment of PCP.[2,11]

PCP must be suspected in HSCT patients presenting with hypoxemia (often disproportionally more severe than the degree of hypercapnia), dyspnea, cough, fever, and bilateral infiltrates,[162,179] especially if noncompliance is suspected or alternative prophylaxis agents have been used. Although it is highly sensitive in patients with HIV infection, measuring the serum lactate dehydrogenase level is less useful in other immunocompromised patients because of low levels of sensitivity and specificity.[190] Serum β-D-glucan levels could potentially be very useful for identifying cases of PCP once the assay has been optimized for use in children.[167] Until then, the definitive diagnosis of PCP still requires identification of the organism on special stains or polymerase chain reaction (PCR) of induced sputum or bronchoalveolar lavage fluid.[162] Once PCP is identified, the treatment of choice is high-dose TMP-SMX (15 to 20 mg TMP/kg/day divided every 6 hours).[163] This high-dose TMP-SMX may be difficult to administer to a patient recovering from HSCT with marginal bone marrow reserves. Therefore, some physicians have used folinic acid "rescue," analogous to what is used after methotrexate administration, with the hypothesis that bacteria are unable to take up the folinic acid from the environment and thus only the host bone marrow cells are helped. Although no data exist in children undergoing HSCT, caution should be taken with this approach because it has been associated with increased treatment failures in patients with HIV infection.[153] Although counterintuitive in a patient with poor T-cell function, TMP-SMX has been combined with a short course of corticosteroids, which appears to be beneficial in preventing temporary worsening of hypoxemia resulting from inflammation from dying organisms. The recommended dose is prednisone 1 mg/kg/dose twice daily (maximum 40 mg twice daily) (or the equivalent dose of methylprednisolone) tapered in half after 5 days and then again in another 5 days, then discontinued after 21 days.[84] It should be noted that these data derive solely from the HIV literature in adults, and it is unclear whether this approach is safe or beneficial in pediatric HSCT patients.

Viral

Viral infections after pediatric HSCT can be divided into two broad categories: DNA viruses that occur as a result of reactivation of a previous infection (and occasionally as a de novo infection) and community-acquired respiratory viruses. Other than donor and recipient serostatus, the major risk factor for reactivation of a dsDNA viral infection after HSCT is the use of T-cell depletion, either ex vivo or in vivo, with serotherapy.[41,127,133] Recently, a few polymorphisms in host immune response genes also have been shown to possibly contribute to the development of dsDNA viral infections after HSCT.[19,20,81]

Herpes Family Viruses

Herpes Simplex Virus. Herpes simplex virus–1 (HSV-1) and HSV-2 infections after HSCT usually occur as a result of reactivations from a previously acquired latent virus. Thus, pretransplant serologies are very useful in identifying at-risk patients. Because acquisition of HSV occurs as patients age, many pediatric HSCT patients will be seronegative. In the era before routine prophylaxis of seropositive patients, reactivation rates were approximately 70 to 80 percent and significantly contributed to post-HSCT mucositis.[156] Dissemination of HSV to the lungs, liver, or brain is also possible. Routine acyclovir prophylaxis is usually given during the period of mucositis, and with this, HSV reactivations are relatively rare.[61] However, severely immunocompromised individuals can continue to develop reactivations for many months after HSCT and thus some centers will continue prophylaxis for up to 6 months,[104] a typical period for development of T-cell reconstitution. This is not needed for patients who receive ganciclovir for CMV prophylaxis, because ganciclovir also has activity against HSV.[62] In addition, some strains of HSV have become acyclovir-resistant, and thus patients with mucositis more severe than anticipated should have a lesion swabbed for HSV culture and resistant strains treated with either foscarnet or cidofovir.[175]

Routine acyclovir prophylaxis does not appear to have a role in HSV-seronegative patients, although consideration of varicella-zoster virus (VZV) serostatus also must be taken into account. Furthermore, patients with B-cell immunodeficiencies may be unable to mount an antibody response before HSV infection and should be considered for prophylaxis, especially if close contacts such as the parents or siblings have a history of HSV infections.

Cytomegalovirus. Historically, one of the most severe complications of allogeneic HSCT was CMV infection. In the modern era, the use of PCR-based detection strategies has significantly reduced the incidence of CMV disease. More than 50 percent of healthy adults in the United States are CMV seropositive, and the incidence increases with age, with 36 percent of children 6 to 11 years of age already exposed.[171] With the use of CMV-negative blood products, the rate of de novo infection in

CMV-seronegative donor and recipient (D–R–) pairs after HSCT is as low as 2 percent.[129] Thus, most infections occur as a result of reactivations, likely of host CMV, because infections are much less common in donor-positive, recipient-negative (D+R–) transplants than in those in which the recipient is positive (D+R+ or D–R+).[129] Other factors can alter the risk for reactivation in a CMV-seropositive HSCT recipient. After autologous HSCT, CMV reactivations are not uncommon, but CMV disease is rare,[195] except in the setting of CD34 selection. T-cell depletion of donor cells in the allogeneic HSCT setting is a major risk factor for reactivation, which may occur even before neutrophil engraftment.[76,184] GVHD and its treatment with corticosteroids and poor T-cell reconstitution, even in the absence of GVHD, are risk factors for CMV reactivation.[18] Of interest, even in the absence of serotherapy, the choice of GVHD prophylaxis regimen may alter the risk for CMV reactivation. Sirolimus, an inhibitor of mammalian (or mechanistic) target of rapamycin (mTOR), appears to provide a protective effect against CMV when used in combination with tacrolimus and in place of other agents.[114] It remains to be determined if this effect is due to direct inhibition of CMV viral replication from sirolimus or enhanced reconstitution of anti-CMV immunity.[114] Overall, as many as 65 percent of seropositive allogeneic HSCT recipients will develop CMV reactivation if not given specific prophylaxis.[51]

Several agents have been used for CMV prophylaxis in at-risk patients (D–R– patients are typically excluded). Because acyclovir has some in vitro activity against CMV, high-dose acyclovir (500 mg/m^2/dose three times daily) has been shown to prevent CMV.[120] Because of its improved absorption, valacyclovir may be superior to high-dose acyclovir for the long-term prevention of CMV reactivation.[103] Ganciclovir is the most commonly used CMV prophylactic agent.[175] As a result of its marrow-suppressive qualities, it is typically started after neutrophil engraftment,[16,196] although some have suggested a role for a therapeutic window during the pre-HSCT conditioning.[124] In addition, ganciclovir use may partially inhibit recovery of both normal and CMV-specific T-cell function.[9] In patients at high risk for early CMV reactivation before neutrophil recovery, foscarnet has been used because of its lack of significant marrow suppression.[8] If prophylaxis is to be used, it is typically continued for 100 days after HSCT,[175] but longer courses may be indicated for patients with significantly impaired immune systems. All of these prophylactic strategies are generally used in combination with screening for reactivation by serum PCR.[175]

Because all of the anti-CMV agents have some degree of toxicity, the alternative strategy to prophylaxis is preemptive treatment based on detection of CMV viremia. A randomized trial comparing prophylaxis versus preemptive management of CMV showed similar outcomes.[16] Patients are screened at least once weekly for CMV DNA and specific antiviral therapy begun once a threshold amount of virus has been detected. Ganciclovir is the most common first-line agent used,[175] although foscarnet can be considered in patients with poor marrow reserve.[148] Even in patients with good marrow function, ganciclovir can cause neutropenia and its use requires monitoring of neutrophil counts and often support with G-CSF.[175] Typically, ganciclovir is given twice daily for a minimum of 2 weeks, or longer for patients whose viremia is still detectable after 2 weeks.[16] Daily maintenance ganciclovir therapy also has been used in patients at high risk for a second reactivation because of poor immune recovery. The duration of maintenance therapy can vary from 4 weeks after first negative PCR result or up to day 100. Oral valganciclovir has become more widely used for preemptive therapy, either as a first-line agent or to replace intravenous ganciclovir at the time of switching to maintenance therapy.[52]

Early in the treatment course, CMV viral loads may rise, but in antiviral-naïve patients this is typically not a sign of resistance. However, continuing increases in viral loads after 2 weeks of therapy or signs of CMV disease should raise suspicion for a resistant strain of CMV. Mutations in the *CMV UL97* phosphotransferase gene typically cause resistance only to ganciclovir, so foscarnet and cidofovir remain alternative agents.[30,48] Mutations in the UL54 viral DNA polymerase will cause resistance to ganciclovir, and cidofovir, and occasionally foscarnet.[48] For the patient who appears be to failing or intolerant of all three drugs, leflunomide is a third-line alternative.[50] Leflunomide is an immunomodulatory agent that inhibits pyrimidine synthesis and results in both antiproliferative and anti-inflammatory effects. The active metabolite appears to inhibit replication of both CMV and human polyomavirus type I, commonly referred to as *BK virus.*

The role of CMV-specific antibodies, either in conventional gammaglobulin products or high-titer products, is of debatable efficacy. On the other hand, efforts to produce donor-derived CMV-specific T cells have shown great promise in treating CMV disease.[53] Given the low rates of GVHD associated with these cells, they may be an upcoming preventive strategy.[139] Furthermore, the techniques that enable generation of CMV-specific T cells also can be used to generate T cells active against Epstein-Barr virus (EBV) and adenoviruses.[71] These so-called trivirus-specific cells represent an exciting avenue of adoptive immunotherapy in severely immunocompromised post-HSCT patients.

Epstein-Barr Virus. EBV infection after HSCT usually results from the reactivation of latent EBV in either residual host B cells or passively transferred donor B cells. As with other herpes family viruses, pre-HSCT serologies can help identify at-risk patients, but because approximately 95 percent of adults are seropositive[13] virtually all patients undergoing adult unrelated-donor HSCT are potentially susceptible. Unlike other herpes family viruses, no clearly effective antiviral agent exists against EBV and thus no post-HSCT prophylaxis strategy exists. Fortunately, the rate of EBV reactivation in patients receiving T-replete grafts is quite low. Conversely, patients who receive ex vivo T cell–depleted stem cells, anti–T-cell serotherapy, and umbilical cord blood grafts have an elevated risk.[60] EBV reactivation can lead to the development of posttransplant lymphoproliferative disease, signs and symptoms of which can include fever, lymphadenopathy, fulminate sepsis, or mass lesions in

lymph nodes, spleen, or central nervous system. Several histologic subtypes exist, and all generally occur within the first 3 to 6 months of the posttransplant period. The first step to be undertaken once an EBV infection is suspected is to reduce immunosuppression when possible.[173] If that fails, because EBV proliferates primarily within B cells, administration of rituximab often is successful at eliminating the infection.[191] Copy numbers of EBV in the blood can be easily monitored after HSCT by PCR, and routine monitoring of high-risk patients is recommended.[175] Less clear, however, is exactly what threshold level should be used for initiation of preemptive therapy, because some patients will have transient self-limited EBV viremia after HSCT.[191] Nevertheless, evidence suggests that preemptive rituximab for treatment of EBV viremia is more effective than initiation once posttransplant proliferative disease is established.[173] Some groups have established methods for enriching for EBV-cytotoxic T lymphocytes, which can both prevent and treat EBV posttransplant proliferative disease in high-risk patients, with little risk for causing GVHD.[118] For centers without access to specific donor T cells, the fact that most donors are EBV seropositive allows the use of unmanipulated donor lymphocyte infusion, which is often effective, albeit with a high risk for inducing GVHD.[77,131]

Varicella-Zoster Virus. With the advent of routine vaccination against VZV at 1 year of age, the majority of immunocompetent patients entering HSCT are seropositive for VZV. In the absence of prophylaxis, reactivations occur in approximately 30 percent of patients after HSCT.[17] A double-blinded trial of acyclovir prophylaxis given for 1 year after HSCT demonstrated a significant reduction in VZV reactivations, although this duration of treatment was inadequate in patients who continued on immunosuppressive therapy for treatment of chronic GVHD.[17] An unresolved question is whether pediatric HSCT recipients who are VZV seropositive before HSCT as a result of prior live-attenuated vaccination, rather than exposure to wild-type VZV, are at a high enough risk for reactivation to warrant long-term prophylaxis. Several case reports suggest that the live-attenuated strain is capable of causing zoster and even disseminated disease in immunocompromised children.[33,101] Therefore, until new data are available, the recommendation for acyclovir prophylaxis should be applied to all VZV-seropositive patients.

For post-HSCT patients who are exposed to an individual with active wild-type VZV infection (including shingles) and are not receiving prophylactic acyclovir or intravenous immunoglobulin (IVIG), passive immunization with varicella-zoster immunoglobulin should be initiated within 96 hours of exposure.[175] There does not appear to be a significant rate of transmission of live-attenuated vaccine strain VZV to immunocompromised individuals, and thus household contacts of HSCT recipients are allowed to receive the vaccine, although optimally it should be given before the HSCT when possible.[175]

According to the 2000 Centers for Disease Control and Prevention recommendations, patients who underwent HSCT were instructed to not be vaccinated with the live-attenuated strains of VZV, thereby placing previously naïve patients at long-term risk for developing a potentially serious infection. However, two reports have since demonstrated the safety and seroconversion rates of the live-attenuated VZV vaccine when given to this patient population after first demonstrating adequate T-cell immune reconstitution.[38,94]

Human Herpesvirus–6. HHV-6 is a ubiquitous pathogen that has infected the majority of people by the age of 2 years and has been reported to reactivate in approximately 50 percent of HSCT recipients according to PCR-based monitoring.[199] The majority of these episodes of viremia appear to be self-limited and asymptomatic, significantly limiting recommendations regarding preemptive therapy. However, a variety of reports have linked HHV-6 reactivations to post-HSCT fevers, rashes, hepatitis, pneumonia, and delayed engraftment.[175] HHV-6 also appears to be a rare cause of post-HSCT encephalitis, typically manifested as memory loss, seizures, hyponatremia, cerebrospinal fluid pleocytosis, and magnetic resonance imaging (MRI) abnormalities in the mesial temporal lobe.[64,157] Patients manifesting these symptoms should have their cerebrospinal fluid examined for HHV-6 by PCR. Recently, HHV-6 replication has been implicated in the initiation of GVHD.[141] When HHV-6–associated disease is diagnosed, ganciclovir is typically the first-line agent, although both foscarnet and cidofovir also have activity against HHV-6.[200] If the HHV-6 viremia does not appear to be resolving with antiviral treatment, the possibility of chromosomally integrated virus must be considered.[82] This can be determined by paired serum and whole blood PCRs and demonstrating that the copy numbers in the whole blood sample are significantly higher and the serum copy numbers are generally very low.

Other Double-Stranded DNA Viruses

Adenovirus. A large number of serotypes of adenovirus have been implicated in causing human disease, and by the age of 5 years most individuals have been exposed to at least one serotype, thereby allowing latent virus to enter the system. Thereafter, reactivation during a period of intense immunosuppression results in the majority of cases of adenoviral viremia after HSCT.[21] The major risk factor for adenoviral reactivation is the degree of immunosuppression experienced by the patient, especially among recipients of T cell–depleted grafts or grafts from unrelated donors and those being treated for GVHD.[32,127] Of interest, for reasons that are not entirely clear, younger age also appears to be a risk factor.[21]

With the advent of PCR-based testing of blood and other body fluids, it has been demonstrated that adenoviral reactivations occur in approximately 27 to 32 percent of pediatric HSCT recipients.[102,127] Because of this high incidence, some centers have now adopted routine screening of blood by PCR for early detection of adenoviral reactivations in high-risk patients.[102] When adenovirus viremia progresses to invasive disease, manifestations include pneumonia, hepatitis, enteritis, cystitis, and nephritis.[21] Adenoviral disease after HSCT has been

associated with mortality rates as high as 78 percent.[127] The only currently available agent for treatment of adenoviral viremia or disease is intravenous cidofovir, typically given on a schedule of three times per week.[78] However, intravenous cidofovir has potentially significant toxicities to both the kidneys and bone marrow. This makes its use as a preemptive agent problematic, especially when some patients appear to spontaneously clear the viremia without treatment.[127,192] An experimental oral liposomal formulation of cidofovir (CMX-001) may potentially be less toxic than the intravenous formulation, and is currently being tested to determine whether it can serve as a preemptive agent. Furthermore, because the major risk factor for the development of adenoviral infection is profound immunosuppression, rapid tapering or withdrawal of immunosuppression, when possible, may potentially play a role in the treatment.[32] For patients who develop adenoviral infection after T cell–depleted HSCT, researchers are working on developing adenovirus-specific T cells for adoptive immunotherapy.[97]

Human Polyomavirus Type I. Human polyomavirus type I, typically referred to as *BK virus*, is a common asymptomatic infection in adults, 90 percent of whom are seropositive.[90] Like other dsDNA viruses, it can reactivate during periods of intense immunosuppression, and between 50 and 80 percent of HSCT recipients will be found to shed BKV in their urine in the first several months after HSCT.[4,147] Much of the time, this viruria is asymptomatic, but BK virus reactivation can be associated with the development of hemorrhagic cystitis (HC) in approximately 5 to 15 percent of HSCT recipients, typically 3 to 6 weeks after HSCT.[10] The patients at highest risk for developing BK virus–associated HC appear to be those who received cyclophosphamide-based conditioning regimens and T cell–depleted grafts.[36] Furthermore, BK virus can be found in the blood of some patients after HSCT and high levels have been associated with the development of BK virus–associated nephropathy,[69] which can be definitively diagnosed only by renal biopsy. Of interest, fluoroquinolone antibiotics inhibit BK viral replication in vitro, and some data suggest that their use as antibacterial prophylaxis after HSCT also may decrease rates of BK virus–associated HC.[100] Decreasing immunosuppression, whenever possible, is the first step toward treating BK virus disease. If the BK virus disease persists, cidofovir is the most commonly used antiviral agent, although leflunomide also appears to have some efficacy[146] and may potentially be better tolerated than cidofovir in patients with significant renal dysfunction.

Respiratory Viruses

Influenza. During seasonal outbreaks, HSCT recipients are at risk for developing influenza infections from close contacts. Although upper respiratory tract symptoms are common, systemic symptoms such as fever or myalgias may be absent.[136] Thus, a high index of suspicion must be maintained during the peak season, because 20 to 50 percent of influenza infections can rapidly progress to lower respiratory tract disease with hypoxemia and a risk for mechanical ventilation and death.[37] Bronchoalveolar lavage may be needed in patients with evidence of lower respiratory tract symptoms, because highly immunosuppressed patients are at risk for harboring multiple pathogens. Preemptive treatment with neuraminidase inhibitors (the choice depending on that year's circulating strain) appears to be relatively efficacious at preventing progress to lower respiratory tract disease.[26] Although the data are limited, combination regimens have been employed for patients with resistant strains or with respiratory failure. No parenteral agent is commercially available in the United States, but several are under investigation or available through emergency use authorization.[2] The use of moderate dosages of corticosteroids to reduce excessive inflammation is controversial,[26] and other forms of immunosuppression should be lowered when possible.

Prevention strategies for influenza center around strict infection control practices, including hand washing, isolation, and eliminating potential exposures via universal vaccination of health care workers, patient family members, and caregivers. If a recent (<2 years or still immunocompromised) HSCT recipient has a significant exposure to a confirmed case of influenza, prophylactic administration of a neuraminidase inhibitor is recommended. This strategy also could be considered if a nosocomial outbreak was to occur on an HSCT unit. Vaccination of HSCT recipients (with the inactivated strain) is highly recommended to occur for several years beginning at 6 months after HSCT, before which time the majority of adult patients are unlikely to mount a response.[26] However, pediatric data are limited, and a fixed 6-month rule fails to take into account the significant variation in immunologic recovery times that occurs among patients depending on stem cell source and presence of GVHD. It is not unreasonable to allow earlier vaccination for patients on tapering doses of immunosuppression,[175] even without documented B-cell function, because a T-cell response to influenza vaccine also may provide some protection.[6] Finally, efforts are under way to create influenza-specific T cells that can be given in a prophylactic fashion following HSCT.[170]

Respiratory Syncytial Virus. During seasonal outbreaks, upper respiratory tract infections from the RNA virus respiratory syncytial virus (RSV) are common in HSCT recipients. Approximately 50 percent of those infected will progress to involve the lower respiratory tract, especially in those with GVHD or severe lymphopenia.[160] Untreated RSV pneumonia in HSCT recipients has a mortality rate approaching 80 percent.[160] Ribavirin, a guanosine analog, is available in aerosolized form for the treatment of RSV. Several potential regimens exist, including a continuous 18-hour infusion and a 2- to 3-hour infusion given three times per day. Because of concerns about potential teratogenicity, it is usually administered in a scavenging tent. Respiratory side effects from inhaled ribavirin are common and include potential bronchoconstriction. Despite its problems and costs, a comprehensive review of inhaled ribavirin treatment in adult HSCT recipients suggests that initiation of ribavirin at the time of diagnosis of RSV upper respiratory tract infection can significantly decrease the risk for progression to lower respiratory tract disease and in those with

lower respiratory tract disease can decrease the risk for death.[160] An oral formulation of ribavirin (used for treating hepatitis C) and an intravenous formulation (not available in the United States) have also been used for treating RSV. However, the data are not conclusive that these formulations are as effective as the inhaled ribavirin.

Palivizumab, an RSV-specific monoclonal antibody, is effective at preventing RSV infections in very young high-risk children. Another potential immunomodulator is IVIG, which often contains anti-RSV antibodies and may decrease RSV-mediated cytokine-induced pulmonary inflammation. A review of the available studies of immunomodulation plus inhaled ribavirin suggests that the combination is superior at preventing progression to lower respiratory tract disease and RSV-related death, than inhaled ribavirin alone.[160] However, because of the small numbers, the report was unable to separate out those who specifically received palivizumab. As a result of this and the lack of any controlled trial, the use of the expensive palivizumab has been questioned. Even more controversial is the prophylactic use of palivizumab. Fortunately, the incidence of RSV infection in the first 100 days after HSCT is still relatively low, at 5.8 percent.[136] However, based on decision-tree analysis, in children undergoing HSCT, it has been estimated that the use of prophylactic palivizumab may increase the absolute survival rate from 83 to 92 percent, suggesting that 12 children would need to be treated to prevent one RSV-related death.[174] Clinical confirmation of this concept is lacking.

Even with "optimal" therapy of inhaled ribavirin plus an immunomodulator, the RSV-attributable mortality in HSCT recipients with lower respiratory tract disease is approximately 25 percent. Therefore, improved treatments are desperately needed and work is under way on higher-affinity monoclonal antibodies, high-titer RSV immune globulin, and antisense compounds.[160]

Other Respiratory Viruses

Other respiratory viruses, including parainfluenza virus,[169] human metapneumovirus,[55] and rhinovirus[123] have been implicated in causing lower respiratory tract disease in HSCT recipients. Risk factors for progression from upper respiratory tract infection to viral pneumonia include acquiring the infection early after HSCT, a low absolute lymphocyte count, and corticosteroid usage.[169] There is no FDA-approved antiviral agent with proved efficacy against these three viruses. However, identifying one of these viruses from the nasopharynx or bronchial washings can be useful in limiting empirical usage of potentially toxic agents to treat other infections, although these viruses often show up as copathogens. Some uncontrolled reports have suggested that inhaled ribavirin may be useful against parainfluenza[31]; however, others have questioned its utility.[130] Recently, a case report demonstrated possible efficacy of DAS18, an inhaled sialidase fusion protein, in an HSCT recipient with severe parainfluenza infection.[34] Ribavirin has in vitro activity against human metapneumovirus, and a recent report suggests that ribavirin may play a role in helping resolve lower respiratory tract disease,[161] although controlled comparisons are lacking. Clearly, the best strategy for dealing with respiratory viral infections after HSCT is to avoid them through careful respiratory isolation.

Protozoa

Toxoplasma gondii

The majority of HSCT programs have dietary counseling in place that eliminates most undercooked meat; thus, toxoplasmosis after HSCT is generally caused by reactivation of previously acquired cysts. Therefore, serologic screening of HSCT candidates can identify most patients at potential risk (excepting those with deficient antibody production),[112] although reports of transmission from white blood cells do exist.[83] In seropositive patients, PCP prophylaxis with TMP-SMX also provides excellent coverage against toxoplasmosis.[112] Patients who cannot tolerate TMP-SMX need careful attention to the possibility of toxoplasmosis, because alternative PCP prophylaxis agents do not appear to provide sufficient protection.[175] For these patients, clindamycin or pyrimethamine combinations can be used as either prophylaxis or preemptive treatment based on PCR for reactivation.[175]

When toxoplasmosis occurs in a post-HSCT patient, the general time frame is 2 to 6 months after HSCT. Because the brain is the most commonly affected organ, fever plus focal neurologic signs, headaches, seizures, or altered mental status, are the typical symptoms that should prompt evaluation for toxoplasmosis. Brain MRI may not always show the characteristic ring-enhancing lesions; therefore, cerebrospinal fluid confirmation should be obtained.[80]

Strongyloides stercoralis

Strongyloides stercoralis is endemic to the tropics and subtropics, including the southeastern United States. Transmission is usually via penetration of the larvae into exposed skin, from which it migrates into the intestines and possibly the lungs. HSCT candidates with intact immune systems may be asymptomatic or have only eosinophilia, and stool testing should be considered for anyone entering HSCT with elevated eosinophil counts.[86] If positive, treatment with ivermectin is generally effective. Infected individuals may begin to show evidence of disseminated disease within 1 to 3 months after HSCT. This can be manifested by diffuse pulmonary infiltrates, often with blood-tinged sputum, or colonic wall penetration, which leads to superinfection with gram-negative enteric organisms.

Cryptosporidium parvum *and* Cryptosporidium hominis

Cryptosporidium spp. are enteric protozoa acquired from contaminated water supplies or livestock that infect intestinal epithelial cells. It causes seasonal transient nonbloody diarrhea and occasional systemic symptoms in healthy hosts and is frequently mistaken for a viral gastroenteritis. In immunocompromised HSCT recipients, however, cryptosporidiosis can cause a chronic severe diarrhea, plus rare biliary tract disease. Multicenter

incidence studies have never been performed, but based on one single-center prospective study, it may be as high as 4 percent of all HSCT recipients and 10 percent of those with diarrhea.[98] Patients with B-cell deficiencies appear to be especially high risk.[98] In HSCT recipients, the symptoms of a *Cryptosporidium* infection can easily be confused with that of intestinal GVHD, and testing for *Cryptosporidium* oocysts should be considered before initiation of additional immunosuppressants.[98] Therapy for *Cryptosporidium* is with paromomycin, azithromycin, or nitazoxanide. HSCT recipients may need combination therapy, and decreases in systemic immunosuppression should be performed when possible.[98]

VACCINATIONS AFTER HEMATOPOIETIC STEM CELL TRANSPLANT

HSCT, especially from an allogeneic donor, involves the creation of a new immune system that lacks protective immunity in regard to vaccines received before the HSCT. Although some memory T and B cells may be passively transferred from the donor at the time of the cell infusion, the majority of the long-term immune system derives from newly generated naïve T and B cells. Therefore, all HSCT recipients require revaccination after recovery of immune function. The major HSCT and infectious disease groups, plus the Centers for Disease Control and Prevention, have published guidelines regarding the timing of vaccine administration,[175] but it has been argued that a "one-size-fits-all" approach, as used in generally healthy infants, is insufficient to produce protective immunity in many HSCT recipients and that the vaccine schedule should be tailored to the individual kinetics of a patient's T and B cell recovery and followed by titers to demonstrate adequate response.[165]

CHAPTER 70

Infections in Pediatric Heart Transplantation

Sheldon L. Kaplan

Each year in the United States, more than 450 children undergo heart transplantation,[75] and infection is an important cause of morbidity and some mortality in these patients. The Registry of the International Society for Heart and Lung Transplantation found that for children who underwent heart transplantation between 1998 and 2010, infection caused by an organism other than cytomegalovirus (CMV) was the cause of mortality in 12.4 percent of patients in the first 30 days after receiving transplants, peaked at 13 percent for 31 days to 1 year after transplantation, and thereafter accounted for 4.1 to 8.6 percent of deaths until more than 10 years after

TABLE 70-1 **Types of Infections Encountered in 332 Children After Heart Transplantation in a Multi-institutional Study***

Type	Number
Bacterial (total)	164
Coagulase-negative staphylococci	25
Enterobacter species	21
Pseudomonas aeruginosa	16
Viral	
Cytomegalovirus	51
Varicella-zoster	11
Respiratory syncytial virus	10
Herpes simplex	6
Other viruses	8
Fungal	19
Candida species	12
Pneumocystis jiroveci	7

*Two hundred seventy-six infections in 136 patients.
Data from Schowengerdt KO, Naftel D, Seib PM, et al. Infection after pediatric heart transplantation; results of a multi-institutional study. *J Heart Lung Transplant* 1997;**16**:1207–16.

transplantation. The Pediatric Heart Transplant Study Group prospectively collected data from 22 pediatric centers in the United States from January 1993 to December 1994 on 332 children younger than 18 years (mean age, 5.5 years) who had undergone heart transplantation.[121] One or more infections (276 total) occurred in 41 percent of the patients (mean follow-up time, 11.8 months) for an average of 0.84 infections per patient; 22 percent had one infection, 8 percent had two infections, and 11 percent had three or more infections during the study period (Table 70-1). In a similar multicenter study in adults who had undergone heart transplantation between January 1990 and June 1991, infections developed in 31 percent of 814 patients, with 22 percent having one infection and 9 percent having two or more infections.[96] Bacterial infections were the most common type of infection occurring after transplantation in pediatric and adult patients.

Immunosuppressive therapy for children who have undergone heart transplantation usually consists of some combination of cyclosporine or tacrolimus, mycophenolate mofetil or azathioprine, and corticosteroids. Sirolimus, an mTOR inhibitor, has been administered to about 10 percent of pediatric heart transplant recipients.[75] Induction immunosuppression may include interleukin-2 receptor antagonists or antithymocyte globulin.[76] Cyclosporine and tacrolimus predominantly block the effect of interleukin-2 on T cells, an action resulting in a diminished T-cell response to mitogen stimulation.[54] The infections seen in heart transplant patients outside the postoperative period generally are a result of this block in T-cell function. Because the types of infections seen in these patients vary with the time elapsed since transplantation, the following discussion is organized in such a manner.

TABLE 70-2 **Evaluation of Children Before Heart Transplantation**

Serology
Cytomegalovirus
Epstein-Barr virus
Toxoplasma gondii
Human immunodeficiency virus
Hepatitis A, B, and C
Rubeola, mumps, rubella, varicella*
Cultures

Skin tests
Purified protein derivative
Freezing of an extra aliquot of serum
Review of the child's immunization status

*For children who are older than 12 months and previously immunized.
†See text for explanation.

PRETRANSPLANTATION EVALUATION

Several infectious agents may be transmitted to the patient via the transplanted organ or can become "reactivated" after transplantation. Determining the antibody status of the recipient and the donor against selected microorganisms (CMV, Epstein-Barr virus [EBV], *Toxoplasma gondii*) helps physicians anticipate or diagnose infections that develop after transplantation. A reasonable pretransplant evaluation for children is outlined in Table 70-2. The child's immunization status is documented, and vaccinations are completed when possible (i.e., hepatitis B vaccine, *Haemophilus influenzae* type b, or *Streptococcus pneumoniae*). The Committee on Infectious Diseases of the American Academy of Pediatrics recommends for immunized children older than age 12 months who are scheduled to undergo solid-organ transplantation that serologic tests be performed for rubeola, mumps, rubella, and varicella to determine whether protective titers are present; if they are not, then vaccination is repeated.[3] If possible, appropriate vaccines should be administered at least 1 month before the patient undergoes transplantation. Evidence of selected active infections is a contraindication for transplantation. Chemoprophylaxis should be considered strongly for children with a positive tuberculin skin test (purified protein derivative). Dental status also is assessed.

In addition to having the routine pretransplant evaluation as outlined in Table 70-2, each patient should be screened carefully for selected infections appropriate to the individual circumstances. If surgery is planned during the respiratory disease season and the patient has respiratory symptoms just before having surgery, screening for influenza virus or respiratory syncytial virus (RSV) by rapid techniques may facilitate prescribing antiviral therapy postoperatively. In areas where community-acquired methicillin-resistant *Staphylococcus aureus* (MRSA) is an important cause of infection, performing surface cultures to detect MRSA colonization may modify the choice of antibiotics used for surgical prophylaxis.[72] Applying mupirocin intranasally may influence the rate of postoperative MRSA infections.[101] In

areas where coccidioidomycosis is endemic, pretransplant serology for *Coccidioides immitis* is recommended; if the result is positive, antifungal prophylaxis is provided.[149] A similar approach for histoplasmosis should be considered.[29] Children from resource-poor countries may harbor *Salmonella* or intestinal parasites asymptomatically, and these organisms can cause serious infection after the child undergoes transplantation. Preoperative stool cultures for enteropathogens and examination of the stool for parasites may alert the clinician that these pathogens are present and could be the cause of postoperative infections.

If the patient is being mechanically ventilated before undergoing transplantation, review of recent tracheal aspirate cultures may help in the selection of empirical antibiotics for initial treatment of suspected nosocomial sepsis or pneumonia. Pretransplant infections associated with procedures such as implantation of ventricular assist devices may require prolonged antibiotic therapy after transplantation is performed.[88,130] These infections typically are caused by common nosocomial pathogens and are not a contraindication to undergoing heart transplantation.

SURGICAL PROPHYLACTIC ANTIBIOTICS

Prophylactic antibiotics typically are administered to patients undergoing heart transplantation surgery. For each institution, selection of prophylactic antibiotics should be based partly on the organisms isolated from postoperative wound infections in that center and the antimicrobial susceptibility of these organisms. Cefazolin generally is a reasonable choice for prophylaxis, unless MRSA is a nosocomial pathogen of concern, in which case vancomycin is suggested.[20] In areas where MRSA is a common community pathogen, vancomycin or some other antibiotic active against MRSA might be considered instead of cefazolin, as determined by preoperative surveillance cultures. Routine use of extended-spectrum cephalosporins is discouraged because it may lead to colonization of the patient by antibiotic-resistant, gram-negative organisms that hyperproduce β-lactamase, such as *Enterobacter cloacae*. Recommendations for the duration of prophylactic antibiotic treatment in these patients are not definite, but some centers continue prophylactic antibiotics for 2 to 5 days or more postoperatively, or until all lines and chest tubes have been removed.

IMMEDIATE POSTOPERATIVE INFECTIONS

Common Infections

During the month after the patient undergoes heart transplantation, the types of infections encountered are the same as those complicating major thoracic surgery. Pneumonia and bacteremia are the most common postoperative infections. The frequency of bacteremia and the distribution of organisms are similar in children and adults after undergoing heart transplantation.[96,121] In a multi-institutional pediatric study, the risk of development of any infection was 25 percent 1 month after transplantation.[121] Overall, 60 episodes of bacteremia occurred in the 136 patients who became infected, and the bloodstream was the most common site of bacterial infection.[122] Lung abscesses and mediastinitis are seen less frequently. Familiarity with the organisms and the antimicrobial susceptibility of isolates recovered from other children in the intensive care units (ICUs) in which these patients receive care helps direct the initial empirical selection of antibiotics.

Postoperative bacteremia is related predominantly to the indwelling lines required for monitoring and infusion of medication. *S. aureus*, coagulase-negative staphylococci, *Enterococcus* spp., and gram-negative enteric organisms such as *Enterobacter* spp., *Pseudomonas aeruginosa*, *Klebsiella* spp., and *Escherichia coli* are the most common causes of nosocomial bacteremia in the pediatric ICU.[67,113] Other foci of infection, such as pneumonia or mediastinitis, also may result in bacteremia.[150] Vancomycin plus an aminoglycoside is a typical antibiotic combination for empirical use for treatment of suggested bacteremia in patients with central lines in place and without focal evidence of infection. Vancomycin therapy should be discontinued as soon as possible if an organism requiring the administration of vancomycin is not isolated.[110] A bacterial line infection may be eradicated successfully without removing the line, but the line should be removed if blood cultures remain positive or the patient's clinical condition deteriorates.[94] Optimally, central lines are removed for *S. aureus* central line–related bloodstream infections.[25] Fungemia, generally with *Candida albicans* or another *Candida* spp., also may be associated with central line–related infections. Central lines complicated by fungemia should be removed immediately.[39,94] Centrally placed lines must be removed as soon as practical so that catheter-associated infections can be prevented.

As in other critically ill children, pneumonia is a particularly common occurrence in heart transplant patients because of the operative site and requirements for intubation and mechanical ventilation. During the first postoperative week, definite bacterial pneumonia developed in 3 of 22 children (14%) in an early study from the University of Pittsburgh Medical Center (UPMC).[58] In the multi-institutional Pediatric Heart Transplant Study Group study, 56 bacterial lung infections were identified, 24 of which developed in patients maintained on a ventilator at the time of transplantation.[121] Nosocomial pneumonia caused by gram-negative bacilli such as *Pseudomonas* and *Enterobacter* or *S. aureus* is especially common in this setting.[113] Daily chest radiographs taken until the patient is released from the ICU may identify pneumonitis before it is clinically suspected. Gram stain and culture of a tracheal aspirate can help guide therapy for lobar pneumonia.

A broad-spectrum combination of antibiotics, such as an extended-spectrum penicillin with a β-lactamase inhibitor (i.e., piperacillin-tazobactam) plus an aminoglycoside, usually is initiated until a pathogen or pathogens are identified. Empirical therapy should be based on the antibiotic susceptibility patterns of the common nosocomial pathogens in the specific ICU in which the

patient is receiving care. Vancomycin also should be considered if MRSA is part of the resident flora in the ICU. Computed tomography (CT) of the chest may detect basilar and retrocardiac pneumonia, which may not be visualized readily by conventional chest radiographs. CT or ultrasonography generally is helpful in assessing the size or characteristics of pleural effusions that may require drainage.

If interstitial pneumonitis is encountered, a more aggressive approach to determining a cause is warranted. Bronchoscopy with bronchoalveolar lavage should be considered strongly. In children who have pulmonary infiltrates after undergoing heart transplantation, flexible bronchoscopy is more useful for establishing a fungal or viral etiology as opposed to a bacterial cause of pneumonia because most patients have received broad-spectrum antibiotics before undergoing the procedure.[140] Lavage fluid is pooled and processed for bacteria including mycobacteria, viruses, fungi, and protozoa by using culture techniques and special stains. Mini bronchoalveolar lavages are commonly employed in some pediatric centers, but how their results compare to a formal bronchoalveolar lavage procedure is not clear and has not been well studied in children.[45] *Legionella* may be an important consideration in some centers.[19,111] Noninfectious causes of pulmonary infiltrates in these children include pulmonary edema, atelectasis, hemorrhage, and adult respiratory distress syndrome.

Urinary tract infections (UTIs) also are common occurrences in the month after undergoing heart transplantation. Urinary catheterization and the immunosuppressive agents contribute to the risk for developing a UTI. Gram-negative enteric organisms (*E. coli*, *Klebsiella pneumoniae*, *P. aeruginosa*, and *Enterobacter* spp.), enterococci, and *Candida* spp. are isolated most commonly. Removal of the catheter as soon as possible minimizes the potential for development of a UTI, which has occurred in approximately 10 percent of adults. In the multi-institutional Pediatric Heart Transplant Study Group study, the urinary tract was the site of 16 bacterial infections.[121] In addition, UTIs developed in three children (14%) at UPMC during the 2 to 3 weeks after undergoing transplantation.[58]

The broad-spectrum antibiotics used to treat the bacterial complications of transplantation promote candidal infection of the urinary tract. Along with removal of the urinary catheter, a short course of intravenous amphotericin B for 10 days or less or of fluconazole with careful dosing because of drug interactions with cyclosporine and tacrolimus is an option for treating candidal cystitis.[105] In some patients, a urine culture positive for *Candida* is a clue that a disseminated candidal infection is present and that further investigation is necessary to exclude the involvement of other organs, especially the kidneys.

Risk factors for early infection in the multi-institutional Pediatric Heart Transplant Study Group study were younger recipient age (particularly <6 months), mechanical ventilation at the time of transplantation, positive donor CMV serology with a CMV-negative recipient, and longer donor ischemic time.[121]

Sternal Wounds and Mediastinitis

Sternal wound infections and mediastinitis occur in less than 5 percent of adult patients receiving modern immunosuppressive therapy for heart transplantation.[73,96,97] Most of these infections occur during the first postoperative month, usually within the first 2 weeks, and are superficial. Almost all are caused by bacteria. Staphylococci and other gram-positive bacteria generally are responsible for 50 percent of cases, and the remainder are caused by a variety of gram-negative bacilli.[97,99] Surgical wound infections developed in eight children in the multi-institutional Pediatric Heart Transplant Study Group study, although the site of the infection was not noted.[121] Over a 15-year period, 15 (0.2%) children at Texas Children's Hospital, Houston, Texas, developed mediastinitis after undergoing cardiac surgery; 2 children had undergone heart transplantation.[143] At another children's hospital, between 1995 and 2003, 3 percent (5 of 165) of children undergoing heart and lung transplantation developed mediastinitis.[83]

Postoperative bleeding requiring reexploration is a risk factor for development of mediastinitis. Fever, incisional pain, and an unstable sternum suggest mediastinitis; however, patients may have no specific evidence of infection, including fever. The white blood cell count may be elevated. A pericardial effusion frequently is detected with the development of mediastinitis, and pericardiocentesis may yield purulent material. CT of the chest may show a fluid collection or abscess within the mediastinum and can detect sternal osteomyelitis. Most cases of mediastinitis are caused by *S. aureus*, coagulase-negative staphylococci, or gram-negative bacteria. Median sternotomy wound infections after repair of a congenital heart lesion occur in less than 1 percent of children in large centers. Mediastinitis caused by gram-negative bacilli in association with pneumonia and bacteremia developed in 3 of the 22 children in the UPMC series; each occurred within 2 weeks postoperatively.[58] Two of the three patients died. *Candida* spp. caused both cases of mediastinitis in the 2 children after heart transplantation. Long and colleagues[83,84] reported that the mediastinitis that developed in the five patients who had undergone heart and lung transplantation was caused by *E. coli*, *Torulopsis glabrata*, *Aspergillus fumigatus*, *Burkholderia cepacia*, and vancomycin-resistant enterococcus.

A superficial median sternotomy wound infection not associated with an unstable sternum can be treated by local drainage of the infected subcutaneous tissue and administration of appropriate antibiotics.[35] Vacuum-assisted closure may be an important aid in addition to antibiotics.[1] A more aggressive approach is required for more serious infections associated with an unstable sternum, mediastinitis, or osteomyelitis of the sternum.[24,35,73] Adequate drainage and débridement of the area are crucial, and any involved wires should be removed. Mediastinal drains usually are kept in place for several days. Some authorities recommend irrigating the drains with povidone-iodine, but the duration of irrigation is uncertain. A reoperation after the initial drainage procedure may be necessary. Pending culture

results, antibiotic therapy is directed against *S. aureus* and gram-negative bacilli. A 4- to 6-week course of antibiotics usually is recommended. Antifungal therapy is initiated if a yeast or fungus is noted on Gram or special stains or isolated from cultures. Careful attention given to surgical technique to minimize postoperative bleeding and early withdrawal of chest and mediastinal tubes placed intraoperatively decrease the incidence of these potentially fatal infections.

Other Infections Encountered During the First Postoperative Month

Herpes Simplex

Herpes simplex infections of the oral mucosa and other superficial surfaces are common after heart transplantation. Oral herpes simplex was observed in 21 percent (11 of 53) of children undergoing transplantation at Stanford University Medical Center.[14] In the multi-institutional Pediatric Heart Transplant Study Group study, only six episodes of herpes simplex infection were noted.[121] Visceral involvement is unusual, although it may develop.[80] Herpes simplex infections typically occur approximately 13 days (range, 0 to 4 months) after transplantation and are reactivation processes, not newly acquired infections.[109] A decrease in lymphocyte transformation in response to viral antigen in vitro may explain the increased rate of infection that occurs in the first 12 weeks post transplantation. In a large randomized study comparing azathioprine with mycophenolate mofetil in adult heart transplant recipients who also were receiving cyclosporine and corticosteroids, herpes simplex infection occurred more commonly in the group treated with mycophenolate mofetil (23% vs. 16%, $p < .05$).[36] Institution of antiviral therapy for herpes simplex infection is warranted in these immunocompromised patients. The most common antiviral agent for herpes simplex is acyclovir, which can be administered orally or intravenously. Valacyclovir dosing in children has been established for children older than age 2 years, but a commercial suspension is unavailable.

Prophylactic acyclovir is recommended by some experts for heart transplant recipients who are seropositive for herpes simplex.[53] Acyclovir is given intravenously during the perioperative period and then orally for 3 to 6 months after transplantation. Other physicians suggest that because labial or oral herpes simplex is treated so easily, a prophylactic approach is not warranted. In view of concern related to toxicity, drug interactions, and the possibility of resistance developing, I favor the approach that targets treatment after a mucocutaneous lesion is noted.

Legionella pneumophila

Legionella pneumophila infection should be included in the differential diagnosis for fever, respiratory symptoms, and pulmonary infiltrates that develop after heart transplantation.[27] *Legionella* pneumonia can develop during the first postoperative month, but the frequency with which this infection occurs varies among transplant centers. Although legionnaires' disease is an uncommon occurrence in children, nosocomial infections have been documented in a children's hospital and immunosuppression is a risk factor.[19,23] Appropriate cultures and direct fluorescent antibody stains for *Legionella* should be performed on sputum, other respiratory secretions (obtained by invasive techniques), pleural fluid, or lung tissue to detect this pathogen in a timely fashion. A *Legionella* urinary antigen test is available for serogroup 1 antigens and is quite sensitive.[141]

Macrolides should be considered for empirical therapy if *Legionella* is a serious consideration in children with nosocomial pneumonia. Erythromycin or azithromycin is provided for 2 weeks to complete therapy. Macrolides interact with many of the immunosuppressive agents administered to these patients, however. Quinolones also are quite active against *Legionella* and avoid many of these interactions; in adult transplant patients, they have become the agents of choice.[141] The use of quinolones should be considered for pediatric organ transplant recipients in whom infection with *L. pneumophila* is suspected. In hospitals caring for patients with transplants, routine surveillance culture of the hospital water supply should be considered.

Respiratory Syncytial Virus

Ten episodes of RSV infection were noted in the multi-institutional study by the Pediatric Heart Transplant Study Group.[121] RSV can be acquired in the hospital soon after undergoing transplantation or can be acquired in the community before undergoing surgery or after discharge. Too few patients in whom RSV infection developed after they underwent heart transplantation have been described to comment on the clinical features. Two children in the early UPMC study[58] were noted to be infected with RSV, with both infections occurring on postoperative day 10. Rapidly progressive patchy infiltrates on chest radiographs developed in one child after undergoing heart-lung transplantation, and the second child had only mild upper respiratory symptoms. Tachypnea, cough, fever, wheezing, and the use of accessory muscles occurred commonly in the 18 pediatric liver transplant recipients from the UPMC with RSV infection.[108] Radiographic changes included interstitial and lobar infiltrates, atelectasis, and pleural effusion in 12 patients. Two patients required mechanical ventilation after the onset of symptoms related to RSV infection occurred; three others were intubated before acquiring RSV infection and subsequently had complicated courses.

Morbidity and mortality rates related to RSV infection are increased in otherwise immunocompetent children with congenital heart disease, especially when associated with pulmonary hypertension.[86] Because RSV can be acquired in the hospital, RSV infection should be considered in a young transplant patient with respiratory symptoms and fever, especially during the colder months.[60] RSV infection is documented by culture or by rapid detection of RSV infection by enzyme-linked immunosorbent assay or fluorescent antibody testing of respiratory secretions.

The decision to administer ribavirin to these patients is based primarily on the severity of the illness. In a small group of children with underlying bronchopulmonary dysplasia or congenital heart disease, aerosolized ribavirin seemed to be associated with more rapid improvement than that in patients given placebo.[61] Administration of aerosolized ribavirin to a heart transplant recipient with proved or suspected moderate to severe RSV infection is reasonable. As is the case with children requiring mechanical ventilation because of severe RSV lower respiratory tract infection, however, the efficacy of ribavirin in this situation is unknown.[135] The 2009 *Red Book* states, "Ribavirin … may be considered for use in select patients with documented, potentially life-threatening RSV infection."[6]

The monoclonal antibody palivizumab was found to be safe, well tolerated, and effective in preventing serious RSV infections in young children with hemodynamically significant congenital heart disease in a large multicenter randomized, double-blind, placebo-controlled trial.[41] Although no specific recommendations have been made regarding the use of palivizumab in children who have undergone heart or other organ transplantation, it would be reasonable to administer it to children 24 months or younger after they undergo heart transplantation and especially postoperatively when the patient is stable.[7] The combination of ribavirin and RSV immunoglobulin has been administered to pediatric bone marrow transplant recipients with RSV lower respiratory tract infection.[31] The outcome in these patients was improved over that of historical controls, but no randomized trials have been conducted. RSV immunoglobulin was not efficacious in treating RSV lower respiratory tract infection in children with congenital heart disease who were younger than 2 years.[114] Although palivizumab reduced the concentration of RSV in the tracheal aspirates of children with respiratory failure caused by RSV, its efficacy in treatment is unknown.[68,89]

INFECTIONS BETWEEN THE FIRST AND SIXTH POSTOPERATIVE MONTHS

Cytomegalovirus

CMV is the virus that most frequently infects immunosuppressed cardiac transplant patients. Asymptomatic or symptomatic infections are noted most often between the first and sixth months after undergoing transplantation and rarely after the seventh month. In adult series, 12 to 90 percent of patients had evidence of CMV infection postoperatively.[34,56,96] In the multi-institutional Pediatric Heart Transplant Study Group study,[121] 51 episodes of CMV infection occurred in 332 patients and accounted for 60 percent of the viral infections, with a peak occurrence in the second month after transplantation. CMV infection occurred more frequently in older children than in infants. In another study, infants younger than 120 days old had CMV infection and disease less often than did infants older than 120 days after undergoing heart transplantation.[46] Maternal antibody to CMV may have been protective in the younger infants. In the UPMC series, seven children (32%) had CMV infections, with onset occurring at a mean of 33 days after transplant (range, 23 to 43 days).[58]

CMV infection in transplant recipients occurs in three or four possible settings. In a seronegative recipient, primary CMV infection is acquired through the transplanted heart, through blood transfusions from seropositive donors, or from community exposure. Seropositive recipients can have reactivation of latent CMV infection or be reinfected with a second strain of CMV from the heart or from blood products derived from seropositive donors.[26,27] The exact site within the donor heart where CMV may reside in a latent form is unknown, but it may be either cardiac cells or leukocytes that remain within the donor heart. When primary CMV infection is acquired from the donor organ, CMV disease tends to be more severe than if CMV infection is acquired from blood or blood products.[155,156]

Several risk factors for development of CMV infection after undergoing organ transplantation are recognized. Donor and recipient serologic status and the immunosuppressive regimen are the most significant risk factors for acquiring CMV infection after undergoing heart transplantation. Gorensek and colleagues[56] found that positive recipient CMV serology before transplantation and a larger than average dose of corticosteroids were significant risk factors for acquiring CMV infection. Among the group of patients with CMV infection, positive recipient serology was associated with asymptomatic infection and excessive corticosteroid dosing was a risk factor for acquiring symptomatic CMV infection. CMV tissue invasion occurred more commonly in patients receiving mycophenolate mofetil compared with azathioprine.

The clinical manifestations of CMV infection vary. Patients may seroconvert, or a latent infection may be reactivated, as determined by positive cultures, but these patients have no symptoms attributable to the CMV infection. Fever, leukopenia, and thrombocytopenia are common postoperative manifestations of systemic CMV infection. Patients may complain of arthralgias, myalgias, and nonspecific abdominal pain. Atypical lymphocytes are noted more often in adult than pediatric patients. CMV infection can cause hepatitis, pneumonitis, retinitis, myocarditis, and gastrointestinal disease, including colitis.* The retinitis may be asymptomatic or associated with complaints such as floaters or scotomas. Ophthalmologic screening for CMV retinitis is recommended by some authorities for all patients 3 to 4 months after cardiac transplantation.[42]

Of the tissues invaded by CMV, involvement of the lung leads to the greatest mortality rate—13 percent in one study.[76] CMV pneumonitis is characterized by fever, hypoxemia, and, usually, diffuse interstitial infiltrates, although lobar consolidation may occur.[128] Pulmonary infections with other viruses or with bacteria or *Pneumocystis jiroveci* and other pathologic processes (infarction) may coexist with CMV pneumonitis. Gastritis, gastric ulceration, duodenitis, esophagitis, pyloric perforation, and colonic hemorrhage can be documented by

*References 34, 40, 42, 55, 56, 71, 129.

endoscopy. In the multi-institutional Pediatric Heart Transplant Study Group study, the lung or gastrointestinal tract was the site of CMV infection in 13 (lung) and 6 (gastrointestinal tract) episodes.[58] Death related to CMV in the pediatric study occurred in 6 percent. In the heart transplant registry spanning 1998 to 2010, CMV was considered the cause of death in 2.7, 0.4, and 0.4 percent of patients 31 days to 1 year, after 3 to 5 years, and after 10 years post transplantation, respectively.[75] In another analysis using a multi-institutional registry of pediatric heart transplantation patients, clinical CMV infection was uncommon in the setting of antiviral and/or CMV antibody prophylaxis.[87]

The diagnosis of CMV infection can be based on changes in antibody titer to CMV in paired sera run in parallel with the use of established tests or on changes in CMV IgM results. Isolation of CMV or detection of CMV DNA from a variety of sources, such as urine, blood, bronchial washings, or tissues, also establishes that CMV infection is present. In a seronegative recipient, the possibility of active CMV infection can be anticipated by periodic monitoring of CMV serology, quantitative blood PCR, or cultures. Whether the CMV infection is causing a symptomatic or invasive illness is more difficult to establish. Histopathologic evidence of CMV infection, such as typical viral inclusions or detection of antigen in tissue by special stains, is required to confirm organ involvement by CMV, although this criterion often is not considered a requirement for clinical trials of preventive measures for CMV disease. Cultures of the buffy coat are positive more frequently in patients with symptomatic than in patients with asymptomatic CMV infection; in patients with primary CMV infection and lung involvement, CMV cultures tend to be positive earlier in the postoperative period than in patients who do not have lung involvement.[56] CMV antigen–positive leukocytes detected by monoclonal antibodies to the early antigen of CMV were found 10 to 28 days before increases in CMV antibody occurred in five patients with active CMV infection.[148] Polymerase chain reaction (PCR) can detect DNA from CMV in blood and other tissues readily and with great sensitivity.[44,48] The antigen and PCR techniques have been used for early detection of CMV infection so that preemptive antiviral therapy can be initiated.[36]

In addition to the CMV infection syndromes, CMV infection itself seems to affect the transplant recipient adversely in other ways. Symptomatic or asymptomatic CMV infection is associated with a higher rate of graft rejection or graft loss, a greater risk of development of fungal infection, more frequent and earlier graft atherosclerosis, and a significantly lower survival rate than occur in patients who do not have CMV infection in some studies.[44,116] In the multi-institutional study, CMV-positive donor serology in conjunction with CMV-negative recipient serology was a risk factor for the acquisition of earlier infection with any organism.[121] More recent studies have not found an association between pretransplant CMV seropositivity and death or coronary artery vasculopathy.[87]

CMV infection of the wide variety of cells that it invades leads to the activation of protein synthesis and the production of multiple immunologically active molecules, including cytokines, especially tumor necrosis factor-α, which adds to the immune deficits induced by the immunosuppressive agents.[44,77] Allograft injury or rejection may be associated with CMV infection of the transplanted organ itself.[44]

Successful treatment or suppression of visceral CMV disease by ganciclovir, a nucleoside analog active in vitro against CMV, requires a timely diagnosis. Ganciclovir has been shown to alter CMV disease favorably in heart transplant patients, along with allowing a reduction in immunosuppressive therapy, when possible.[74] The standard approach for treating symptomatic CMV infection is administration of 2 to 3 weeks of intravenous ganciclovir, although the optimal duration of this therapy and the need for maintenance oral doses are unclear.[117] The dosage is 5 mg/kg every 12 hours with careful monitoring of hematologic parameters and renal function if renal function initially is normal. Modification of the dose is necessary if renal function is impaired. Viremia should be cleared before discontinuing therapy.[44] The most common adverse reactions to ganciclovir are neutropenia, thrombocytopenia, impaired renal function, seizures, and other central nervous system (CNS) abnormalities.

The role of CMV hyperimmunoglobulin in treating CMV infection in these patients requires further study. After bone marrow transplantation, the addition of CMV immunoglobulin to ganciclovir may be superior to ganciclovir alone in treating CMV pneumonia.[38,112]

In one pediatric study, symptomatic CMV disease developed in five children after they had undergone heart transplantation; each had blood cultures and PCR positive for CMV.[51] Four were treated with ganciclovir for 14 days; one received ganciclovir for 30 days. All received CMV-IgG (150 mg/kg) weekly for 3 weeks. Symptomatic CMV disease was treated successfully in each case.

If possible, prevention of CMV infection in heart transplant recipients is optimal. Only seronegative blood should be used for transfusions when the recipient and the donor are seronegative. Careful control of immunosuppressive therapy, especially with corticosteroids, may help avoid the acquisition of some infections. In the situation of a seronegative recipient of a heart from a seropositive donor, prophylactic administration of CMV immunoglobulin may be useful. In one study involving the prevention of CMV disease, ganciclovir was compared with CMV immunoglobulin (misoprostol [Cytotec]) in 31 CMV-seropositive heart transplant recipients in whom OKT3 monoclonal antibody was used for early immunoprophylaxis.[2] CMV disease and visceral involvement occurred more frequently in the group given CMV immunoglobulin (40%) than in the group given ganciclovir (6%; $p = .03$). CMV-IgG would be expected to be more beneficial in recipients who are seronegative to CMV.

In one large randomized double-blind, placebo-controlled trial of CMV-seropositive transplant recipients, ganciclovir significantly reduced the incidence of CMV illness during the first 120 days after heart transplantation (9% vs. 46% in controls, $p < .001$).[93] No differences were noted between the study groups for seronegative recipients. Combining ganciclovir and CMV-IgG for

prophylaxis of high-risk seronegative recipients of hearts from seropositive donors has resulted in mixed findings. Avery[11] found that the combination was not particularly effective; symptomatic CMV syndrome developed in 50 percent of patients. Garjarski and associates[48] provided CMV-IgG 150 mg/kg intravenously at weeks 0, 2, 4, 6, and 8, and 100 mg/kg intravenously at weeks 12 and 16 plus ganciclovir 5 mg/kg every 12 hours intravenously for weeks 1 and 2 and 6 mg/kg/day intravenously at weeks 3 and 4 to 19 children who were recipients of heart transplants from CMV-seropositive donors. CMV disease occurred in 3 of the 10 children who were CMV seronegative and in 1 of the 10 recipients who were seropositive. Adverse effects of these agents were not reported.

In the study from Stanford University Medical Center, high-risk recipients received CMV-IgG immediately after undergoing transplantation (150 mg/kg administered within 72 hours after transplantation, followed by 100 mg/kg at weeks 2, 4, 6, and 8, and 50 mg/kg at weeks 12 and 16).[146,147] In addition, ganciclovir was administered intravenously immediately after transplantation at a dose of 5 mg/kg every 12 hours for 14 days, followed by 6 mg/kg/day for the next 2 weeks. These patients were compared with a historical control group at the same institution who received ganciclovir in the 2 to 3 years before CMV-IgG was used. The 27 recipients treated prophylactically with ganciclovir and CMV-IgG had a higher disease-free incidence of CMV, a lower incidence of rejection, and a higher survival rate than those of the historical cohort treated with ganciclovir alone. Data from the Scientific Registry of Transplant Recipients indicated that for children undergoing heart transplantation, CMV-IgG with or without ganciclovir and ganciclovir with or without CMV-IgG were associated with significant reduction in graft loss and deaths versus no prophylaxis.[136] The combination looks promising for prevention of CMV disease in high-risk heart transplant recipients but a randomized trial is required before the combination can be recommended routinely.

CMV resistant to ganciclovir may emerge as a result of ganciclovir prophylaxis or treatment.[13,16] Foscarnet or cidofovir is an alternative agent in this situation.

In a meta-analysis of CMV prevention strategies for posttransplantation CMV disease, Small and associates[134,136] concluded that universal prophylaxis and preemptive approaches are equally effective in reducing the incidence of CMV disease.

Epstein-Barr Virus

EBV may cause a spectrum of diseases, including a mononucleosis-like syndrome, polyclonal lymphoproliferation, or monoclonal lymphoproliferation, usually of B cells, in pediatric heart transplant recipients. The transplanted organ is thought to be the most frequent source of EBV. Posttransplantation lymphoproliferative disorders (PTLDs) refer to B-cell expansion that may be localized, nodal, extranodal, or widely disseminated. The largest series of children who have undergone heart transplantation is from the UPMC; in this series, PTLD developed in 7.7 percent (6 of 78) of pediatric heart transplant recipients.[18] A major risk factor for the subsequent development of PTLD was being seronegative for EBV before undergoing transplantation. PTLD developed in one third of seronegative recipients of thoracic organs who acquired primary EBV infection (10 of 30). PTLD developed in none of the children who were seropositive before transplantation. Almost all these cases occurred within 1 year of transplantation.

In another series, 19 children were EBV seropositive and 31 were EBV seronegative before undergoing heart transplantation. PTLD developed in 1 of 19 patients who were seropositive before undergoing transplantation and in 12 of 19 who became seropositive after transplantation.[158] It did not develop in any of the 12 recipients who remained EBV seronegative. In contrast to the UPMC experience, the mean time to confirmation of PTLD was 29 months (range 3 to 72 months).

Webber and associates[153,154] reviewed the experience with PTLD after heart transplantation among 1184 primary organ recipients in 19 centers from 1993 to 2002. Fifty-six patients (5%) developed PTLD a mean of 23.8 months post transplantation. In a study from Germany, 12 of 147 (8.2%) developed PTLD a mean of 3.2 ± 2.2 years post transplantation.[123] Among 173 heart transplant recipients at the University of Toronto Hospital, 23 (13.3%) developed PTLD within a median of 4 years post transplantation.[90] Higher maximum EBV viral load and longer duration of induction therapy were associated with increased risk of PTLD. In the largest study among a multicenter group, PTLD developed in about 5 percent of 2374 children.[47] Pretransplant seropositivity for EBV and the receipt of induction treatment except OKT3 was associated with a reduced risk of developing PTLD.

Symptoms of PTLD may include fever, malaise, sore throat, and lymphadenopathy. Some children may have splenomegaly, CNS symptoms such as lethargy or seizures, or gastrointestinal complaints.[16,18] Concurrent opportunistic infections are common. Nodules in the lung may be noted on chest radiographs.

The diagnosis of PTLD requires biopsy of involved tissue showing lymphoid proliferation with an immunoblastic component. Molecular techniques typically detect EBV nucleic acids in tissue. EBV serology also is helpful. Quantitative measurement of EBV DNA and RNA in peripheral blood is used to detect primary infection or reactivation at a very early time point and to monitor viral loads serially over time to detect PTLD in the most timely manner.[115] When reported as EBV copies per 10^5 peripheral blood lymphocytes, patients with PTLD typically have viral loads between 500 and 5000, which are much greater than the loads detected in normal latency.

Management generally involves decreasing the immunosuppressive regimen or discontinuing it temporarily. Anti-CD20 antibody (rituximab) is a commercially available monoclonal antibody that specifically binds to the CD20 antigen of normal and malignant B cells and results in antibody-dependent and complement-dependent cytotoxicity. Rituximab has been administered with success to children and adults with PTLD after they have undergone solid-organ transplantation.[37,123,125,126] Antiviral therapy with acyclovir or ganciclovir also is

administered. Some centers administer ganciclovir, acyclovir, or intravenous gamma-globulin for prevention of PTLD, although no prospective studies have confirmed that such an approach is efficacious.[57]

Toxoplasma gondii

An increased incidence of toxoplasmosis is apparent in recipients of heart transplants compared with other organ transplants, although it remains an uncommon infection after heart transplantation.[138] In the multi-institutional study by the Pediatric Heart Transplant Study Group,[121] toxoplasmosis was not mentioned. *T. gondii* has a predilection for muscle and can be transmitted to the recipient from the heart of a seropositive donor. Active *T. gondii* infections may occur in donor hearts.[118] Less commonly, reactivation of old infection occurs in the recipient. The greatest risk for acquisition of toxoplasmosis occurs in a seronegative recipient of a heart from a seropositive donor. Clinical symptoms usually develop after the first postoperative month and generally within 3 months of transplantation.[62,85,95] Fever alone may be the only clinical manifestation. Dissemination of the parasite to the CNS may lead to signs and symptoms of meningoencephalitis, such as lethargy, seizures, coma, and hemiparesis. Chorioretinitis may result in diminished visual acuity. A sepsis-like picture, pneumonia, and cutaneous lesions are unusual manifestations.[10]

CT or magnetic resonance imaging of the brain may detect ring-enhancing mass lesions, which typically are multiple and in periventricular locations. Definitive diagnosis of CNS toxoplasmosis requires the demonstration of tachyzoites or cysts in tissue by biopsy or at necropsy. Serologic tests help monitor seronegative patients for seroconversion and allow a more aggressive approach to be taken to the early diagnosis of toxoplasmosis.[133] *T. gondii* has been seen on endomyocardial biopsy specimens routinely obtained to monitor for rejection.[84]

Therapy for toxoplasmosis with pyrimethamine and sulfadiazine may lead to recovery; these drugs also should be administered if the patient seroconverts.[49] Prophylactic administration of pyrimethamine to seronegative recipients of hearts from seropositive donors is recommended.[157] Prophylactic trimethoprim-sulfamethoxazole also seems to be protective in this high-risk situation.[12,99] Spiramycin is not a useful prophylactic agent.[133]

Aspergillus fumigatus

A. fumigatus is the non-*Candida* fungal infection most commonly reported outside the immediate postoperative period in most series and may be noted first at necropsy.[106] In a report from Stanford University Medical Center,[57] *Aspergillus* infections developed in 620 consecutive heart transplant recipients between 1980 and 1996.[99] Most commonly, *Aspergillus* infections were in the lung (31 recipients) or were disseminated (17 recipients). The median time to onset was 52 days. Disseminated aspergillosis was the most common infectious episode responsible for the highest mortality rates in this series. One child in Pittsburgh had disseminated aspergillosis.[58] In the multi-institutional study by the Pediatric Heart Transplant Study Group, seven non-*Candida* fungal infections occurred: *Aspergillus* spp., two; *Cryptococcus*, *Rhizopus*, and *Rhizomucor*, one each; and unspecified, two.[121] All patients with disseminated infection died. Among 1854 children in the Pediatric Heart Transplant Study, 18 had infection due to *Aspergillus* spp. (including 9 with pulmonary and 5 with cutaneous infections).[159] Risk was highest in the first 6 months after transplantation; prior surgery and the need for mechanical ventilation at transplant were independent risk factors for invasive fungal infection.

CNS invasion occurs in many patients with pulmonary aspergillosis, and aspergillosis is the most common cause of brain abscess in organ transplant recipients.[62,98,132] Alterations in mental status occur most frequently, and seizures may occur in 40 percent of cases. Multifocal lesions are seen commonly on CT of head and show a predilection for the junction of the gray and white matter. Mediastinitis and endocarditis are other manifestations of invasive aspergillosis.[81,126] Although isolation of *Aspergillus* from respiratory secretions in a patient with pneumonitis does not establish a diagnosis, aspergillosis is so difficult to establish firmly and is so frequently fatal that treatment should be considered seriously based on this culture alone. Serial measurement of serum galactomannan levels may help in recognizing this infection. Measuring the galactomannan in the bronchoalveolar lavage fluid may also detect evidence of invasive pulmonary aspergillosis in solid-organ transplant patients, perhaps leading to earlier administration of antifungal therapy.[28]

Voriconazole is the agent of choice for invasive aspergillosis.[64,151] The reader is referred to Chapter 197 on aspergillosis and the Infectious Diseases Society of America clinical guidelines for recommendations regarding therapy.[151]

INFECTIONS AFTER THE SIXTH POSTOPERATIVE MONTH

Nocardia asteroides

A dry cough, fever, and the presence of a solitary pulmonary nodule or abscess on a chest radiograph are characteristic of infection with *N. asteroides*.[79,131] Although pulmonary nodules are characteristic of *Nocardia*, *Aspergillus* and CMV can be associated with nodules as well.[99] Some patients are asymptomatic despite having an abnormal chest radiograph. Infection with *Nocardia* was noted in only 3 percent of cyclosporine-treated patients in the early Stanford University Medical Center series.[65] The median time to the onset of infection was 225 days. A similar incidence of lung nodules or masses secondary to *Nocardia* was noted in a series from New York.[63] In the follow-up Stanford series, 23 episodes of *Nocardia* infection (3.7%) occurred, with 19 in the lung.[99] The median time of onset of infection in the second series was 147 days. *Nocardia* infections are rare in pediatric heart transplant recipients.

Nocardia is isolated best from direct lung tissue specimens, but it also may be cultured from bone, skin, or

other sites of involvement. If a cutaneous skin lesion of *Nocardia* is recognized, other sites should be evaluated promptly for involvement.[52,54] The formation of single or multiple abscesses in the CNS may result from hematogenous dissemination.[64] Seizures may develop after invasion of brain parenchyma.

The drug of choice for treating *N. asteroides* infection is a sulfonamide. Prolonged administration (average 10 months) generally leads to clearing of the pulmonary lesions. Minocycline is an alternative therapeutic agent.[107] The incidence of *Nocardia* infection has declined with the introduction of routine prophylaxis with trimethoprim-sulfamethoxazole.

Pneumocystis jiroveci

P. jiroveci (formerly *P. carinii*) pneumonia has been reported in 3 to 4 percent of heart transplantation recipients during the postcyclosporine era.[43,59,65] In the multiinstitutional study of the Pediatric Heart Transplant Study Group, *P. carinii* was noted in seven children (2.1%).[121] In the Pediatric Heart Transplant Study, 18 of 1854 patients (1%) had *P. jiroveci* infection. Ninety-five percent of these infections occurred between 2 months and 2 years after transplantation.[100] Fever, a nonproductive cough, and tachypnea are typical symptoms; hypoxemia is characteristic.[159] The chest radiograph classically shows a diffuse interstitial infiltrate that can progress rapidly. The most expeditious method of documenting *P. jiroveci* pneumonia in children is with methenamine silver or specific antibody staining of fluid or tissue obtained by bronchoalveolar lavage or lung biopsy.

Elevation in serum β-D-glucan concentration can be a clue to this infection. Coinfection with CMV or other pathogens occurs commonly.

Treatment of *Pneumocystis* pneumonia in a pediatric heart transplant recipient is identical to that for other immunocompromised children. Use of trimethoprim-sulfamethoxazole prophylaxis for at least 4 months after transplantation has decreased markedly the incidence of this infection in recipients of heart transplants.[103] Only one patient died in the Pediatric Heart Transplant Study Group study as a result of *Pneumocystis* pneumonia.[100]

Streptococcus pneumoniae

S. pneumoniae is an important community-acquired pathogen in heart transplant recipients, who are at increased risk for acquiring this organism.[8] In the multiinstitutional Pediatric Heart Transplant Study Group study, two episodes of pneumococcal infection were recorded.[121] During a 10-year period, 9 (11%) of 80 cardiac transplant patients in Little Rock, Arkansas, had 12 episodes of pneumococcal bacteremia.[142] Over an 11-year period, 4 of 105 children undergoing heart transplantation in Toronto had systemic pneumococcal infections.[144] In the follow-up series from Stanford University Medical Center, seven pulmonary infections with *S. pneumoniae* were reported.[99] In an eight-center pediatric surveillance study spanning 5 years, pneumococcal infection developed in 10 patients after a median time from transplantation of 17 months (range, 5 to 76 months).[124] Three of the 10 patients had two episodes, and one patient had three episodes of pneumococcal infection. The median age of the 10 patients at the time of the first pneumococcal infection was 26 months (range, 15 to 89 months). The pneumococcal serotypes of the isolates from these patients were the same as noted in healthy children and generally would be covered by the 23-valent pneumococcal vaccine or the 13-valent pneumococcal conjugate vaccine.

Other Viruses

Influenza and parainfluenza viruses can cause serious infections at any time after transplantation, but especially in the immediate postoperative period.[9,91] Additional risk factors for development of severe disease leading to death are young age and augmentation of immunosuppression. Fever, cough, rhinorrhea, and pharyngitis are typical symptoms of upper respiratory tract infections. More serious manifestations include adult respiratory distress syndrome, a requirement for intubation and mechanical ventilation, a sepsis-like picture, or CNS symptoms such as headache, photophobia, and lethargy. Viral infection may enhance the likelihood of allograft rejection.

For influenza A infection, oseltamivir, amantadine, or rimantadine should be considered in younger children older than 12 months of age with a heart transplant because of their enhanced predisposition for severe or complicated influenza infection.[8] In older children, zanamivir or oseltamivir is indicated. Recommendations vary depending on the susceptibility of the circulating influenza strains, and thus the treating physician needs to be aware of this information.

Parvovirus B19 infection is recognized to cause severe anemia associated with low or no reticulocytes in recipients of heart transplants, similar to the red blood cell suppression in other immunosuppressed patients.[102] In one child, severe pneumonia developed in association with fever and a blanching maculopapular rash involving the face, trunk, and extremities.[69] The parvovirus B19 genome also has been detected in myocardial biopsy specimens of children experiencing cardiac allograft rejection. Of six children described in one report, one had a diffuse rash and two had persistent rejection despite receiving aggressive therapy.[122] In a series of children from Loma Linda University Medical Center who underwent myocardial biopsy for possible rejection, parvovirus genome was detected in 5 of 553 biopsy samples taken from 149 children.[127] The genome parvovirus B19 was the most commonly detected viral genome in endomyocardial biopsy specimens from 99 children in one study.[21] The detection of parvovirus B19 genome did not correlate with cellular rejection, but if it was present chronically there was an association with transplant coronary artery disease. Intravenous immunoglobulin is beneficial for the treatment of anemia related to parvovirus B19, but its efficacy in treating pneumonia or possible allograft rejection is unknown.[70]

Varicella virus infection remains a common childhood illness that can cause life-threatening disease in

immunocompromised children. In a group of 28 children younger than 10 years old at the time of undergoing heart transplantation who had been monitored for at least 1 year between 1986 and 1999, 14 cases of primary infection with varicella-zoster virus were identified.[33] The mean time after transplant was 3 years (range, 9 months to 7.5 years). All children were seronegative at the time of transplantation. These children were treated successfully with either parenteral therapy followed by oral acyclovir or oral valacyclovir (mean dose, 77 mg/kg/day) for 7 days. Only one child had recurrent varicella, and none had zoster. Routine administration of varicella vaccine to young children helps to decrease most concerns about varicella developing after organ transplantation because of herd protection. Some patients do lose serologically measured immunity to varicella after undergoing transplantation, especially those children who undergo a transplant in the first 2 years of life.[145,152]

Adenovirus has been associated with serious infections after solid-organ transplantation. Among 28 children with solid-organ transplants (9 with heart transplants) and adenoviral infections, the most common symptoms were fever, diarrhea, vomiting, and abdominal pain.[30] Infection occurred a median of 1.6 months after transplantation. Only 2 of these children received antiviral therapy, and all survived the infection. Cidofovir may be beneficial in some patients with disseminated infection, especially of the lungs, or increasing viral loads determined by PCR.[33,66]

IMMUNOSUPPRESSIVE AGENTS AND ANTIBIOTICS

Cyclosporine and tacrolimus have improved the success of organ transplantation considerably. Generally, the incidence of infection seems to be less since the introduction of cyclosporine than with the earlier immunosuppressive regimens, although morbidity rates remain high in heart transplant recipients. Cyclosporine serum levels are monitored carefully to ensure that concentrations associated with optimal immunosuppression and minimal adverse effects are maintained. Some antibiotics interfere with the pharmacokinetics of cyclosporine or tacrolimus, which may lead to an increase or decrease in their levels.* These interactions are outlined in Table 70-3. Because cyclosporine and tacrolimus are nephrotoxic, the antimicrobial agents (amphotericin B, aminoglycosides, acyclovir, ceftazidime) administered to heart transplant recipients may be additive; renal function must be monitored carefully.

TABLE 70-3 **Effect of Various Antibiotics on Cyclosporine/Tacrolimus Levels**

Increased Level	Decreased Level
Clarithromycin	Sulfadiazine
Azithromycin	Rifampin
Erythromycin	Trimethoprim-sulfamethoxazole
Ketoconazole	? Nafcillin
Fluconazole	? Isoniazid
Itraconazole	? Ciprofloxacin (counteracts immunosuppression)
Posaconazole	
Voriconazole	
Caspofungin	

IMMUNIZATIONS

No specific guidelines exist for the immunization of children after they have received a heart transplant, although studies examining the immunogenicity of selected vaccines in this population are being conducted. A prudent approach is to follow the recommendations that the Committee on Infectious Diseases of the American Academy of Pediatrics has developed for immunizing immunosuppressed children.[4] Ideally, the patient will have received the recommended routine vaccines before undergoing transplantation.

Children who have received transplants before reaching 2 to 3 years of age do not respond to the pneumococcal polysaccharide vaccine as well as do children who are older when they receive a transplanted heart, even though the vaccine is administered several years after they receive the transplant.[51] An impairment in immunoglobulin isotype switching from IgM to IgG and especially IgG2 seems to result from the immunosuppressive therapy that these children are receiving.[50] In one study, the antibody response of children aged 2 to 18 months old after solid-organ transplantation was compared with age-matched children to the 7-valent pneumococcal conjugate vaccine (PCV7) followed by the 23-valent polysaccharide vaccine (PV23) 2 months later.[82] The antibody levels achieved were significantly higher in the controls, and a second dose of PCV7 given 2 months after the administration of the first PCV7 dose did not lead to higher antibody levels.

For previously unimmunized transplant recipients aged 2 to 18 years old, conjugate pneumococcal vaccine is recommended, followed by the 23-valent pneumococcal vaccine at least 2 to 12 months later. Ideally, children will have completed their PCV7 series before undergoing transplantation.[5] Ongoing immunosuppression seems to prevent maturation of the response to polysaccharide antigens in younger children, which it is hoped that the conjugate vaccine can overcome. The PV23 is less immunogenic in adults after they have undergone heart transplantation than it is in healthy controls.

Antibodies to the influenza vaccine develop in most children, but previous exposure predicts a better response.[92] Annual administration of influenza vaccine seems to be safe and immunogenic in children after they have undergone solid-organ transplantation. In one study, low-level histologic rejection occurred after the administration of influenza vaccine.[17] In a later study, the administration of inactivated influenza vaccine was not

*References 15, 21, 78, 104, 119, 120, 137, 139.

associated with an increased risk of rejection.[155] Depending on the time of year and the approximate date of transplantation, influenza vaccination is appropriate for the patient and all household contacts and health care workers to whom the patient might be exposed. The live-attenuated influenza vaccine is not recommended for individuals receiving immunosuppressive therapy or their close contacts.

After transplantation has been performed and after immunosuppressive therapy has been initiated, administration of live viral vaccines is contraindicated. The enhanced inactivated polio vaccine should be given to the child and to normal siblings. Measles, mumps, rubella, and varicella vaccines can be given to the siblings. Diphtheria, tetanus, and acellular pertussis inactivated vaccines should be given at the routine booster schedule, although antibody responses may not be equivalent to those observed in normal children. Varicella vaccine should be administered before transplantation is performed, if varicella antibody is not detected at the pretransplant evaluation in a child aged 12 months or older. Whether the antibody response data generated in children with leukemia during maintenance chemotherapy can be applied to heart transplant recipients who must continue daily immunosuppressive therapy is unclear.

CHAPTER 71

Infections in Pediatric Lung Transplantation

Jill A. Hoffman

The first pediatric lung transplant was reported to the International Society for Heart and Lung Transplantation (ISHLT) in 1986; and by the end of 2009, a total of 1664 transplants had been reported to the registry, with 127 performed in 2009.[57] Although this represents an increase over time worldwide, there has been a decrease in these transplant procedures in the United States from 42 in 1998 to 20 in 2009.[511] The reasons for this decline are likely multifactorial, but a primary one is the increased survival of persons with cystic fibrosis (CF), which is the leading indication for pediatric lung transplantation; life expectancies for these persons are now into the fifth and sixth decades for infants born in 2000.[136,186] This reflects improvements in therapy and the effect of widespread neonatal screening.[264,639] In addition, some controversy exists on the survival benefit of transplantation for patients with CF.[7,218] Transplantation is not a cure for the lung disease of persons with CF, and the factors that predict optimal timing of transplant to maximize survival and quality of life are not entirely defined. Living lobar transplantation (LLT) has been performed at some centers as a way to address the shortage of available organs,[645,665,714,738]; the number of these procedures peaked in 1999 and all of the pediatric lung transplantation procedures performed in the United States in 2007 to 2009 used lobes from deceased donors. At Children's Hospital Los Angeles (CHLA), the first pediatric LLT was performed in 1993 on a 13-year-old boy with CF. He received lobes from each of his parents and survived for 5 years, unfortunately succumbing to renal failure while waiting for a kidney transplant.[738] Fifty-five LLT procedures (49% of 113 total-lung and 12 heart-lung transplants) have been performed on pediatric patients at CHLA to date.[300]

The primary indication for lung transplantation in the pediatric population remains CF—20 percent in the United States (2007-2009), followed by 13 percent each for primary pulmonary hypertension and obliterative bronchiolitis.[511] From 2000 to 2010 in the United States, 55 percent of transplants were in patients with CF, compared with 75 percent in Europe. Worldwide, 56 percent of 6- to 11-year-olds and 72 percent of 12- to 17-year-olds underwent transplants for this indication. Most pediatric transplant recipients are adolescents (>70%).[57,433] For younger children, the most common diagnoses were surfactant B deficiency and complex congenital heart disease in infants younger than age 1 year undergoing lung transplantation and primary pulmonary hypertension in children aged 1 to 5 years.[57,85]

Infectious morbidity and mortality remain high for lung transplant recipients.[17] This incidence results from constant communication of the lungs and fresh bronchial anastomosis with the environment and from the high preoperative microbial burden of patients with CF. Denervation of the transplanted lung, interruption of the bronchial and lymphatic circulation, abnormal cough reflexes, and impaired mucociliary clearance also probably play roles.[17] In addition, these patients receive relatively high-dose, long-term immunosuppression; at 5 years, most patients still are maintained on mycophenolate mofetil (55%), tacrolimus (70%), and corticosteroids (98%).[57] In the first year after lung transplantation at CHLA, the overall incidence of infection was 0.24 episode per patient per month, or 2.88 infections per patient per year.[394] Fifty-five percent of all infections occurred in the first month after transplantation, with infections becoming much less frequent thereafter (Table 71-1).[394] A summary of the causes of infection in this cohort during the first year after transplantation is presented in Tables 71-2 and 71-3.[394]

The additional indirect impact of infections on the outcome of lung transplant recipients is also recognized. Cytomegalovirus (CMV) and other viruses, as well as bacterial infections, have been implicated in immunologically mediated processes leading to bronchiolitis obliterans syndrome or chronic graft dysfunction, acute rejection, graft loss, and death (see later discussion).[17,57]

The overall survival of pediatric lung transplant recipients (2002-2009, n = 653) as reported to the ISHLT is 84, 65, 53, and 45 percent at 1, 3, 5, and 7 years, respectively. This survival is similar to that of adult recipients, with a transplant half-life (50% mortality in recipients) of 5.5 years.[57] There is no difference in survival according to donor lung source (i.e., living vs. deceased).[52,665,714] Infection is the single most common cause of death from 1 month to 1 year after transplantation (46%), and it remains a significant cause of death in all periods through 5 years after transplantation.[57] Bronchiolitis obliterans syndrome causes approximately 40 percent of deaths after the first year. Graft failure accounts for a third of deaths in the first month and 13 to 25 percent thereafter.[4] In the series of 75 pediatric transplants at CHLA (12 heart-lung, 18 cadaveric, 45 LLTs), the mortality rate was 18.6 percent at 1 year, 50 percent of which was attributed to infection.[394]

TABLE 71-1 **Etiology of Infections in 75 Pediatric Lung Transplant Recipients in the First Postoperative Month at Children's Hospital Los Angeles**

Etiology	Number of Episodes
Pseudomonas, respiratory tract	22
Candida, respiratory tract	13
Herpes stomatitis	12
Cytomegalovirus infection	10
Aspergillus infection of the respiratory tract, bronchial anastomosis	4

TABLE 71-2 **Etiology of Infections in 75 Pediatric Lung Transplant Recipients in the First Year at Children's Hospital Los Angeles**

Etiology	% of Total Infections
Bacterial infections	55
Pseudomonas spp.	18 (35% of bacterial infections)
Viral	27
Cytomegalovirus	12 (42% of viral infections)
Fungal	16
Candida	10
Aspergillus	4

TABLE 71-3 **Timetable of Infections for Pediatric Lung Transplant Recipients**

Time of Initial Evaluation	Infection/Pathogen	Comments
0-1 Month	Wound, respiratory tract, line/bloodstream, and urinary tract infections	Related to the surgical procedure: *Candida, Staphylococcus* spp., *Pseudomonas* spp.
	HSV stomatitis	Reactivation
	CMV infection	
	HHV-6?	
	Bronchial anastomosis *(Aspergillus)*	
	Other: rabies, West Nile virus, lymphocytic choriomeningitis virus, endemic mycoses	Unusual pathogens preexisting in the recipient or in the donor graft
1-6 Months	CMV disease	Onset of opportunistic infections from immunosuppression
	EBV	
	Aspergillus	
	Mycobacterium tuberculosis	
	Pneumocystis jiroveci	
	Endemic mycoses	
	HHV-6	
	Respiratory tract, line/bloodstream, and urinary tract infections	Continued bacterial *(Pseudomonas)* and candidal infections common through 3-4 months
	Respiratory viruses	Community-acquired infections
>6 Months	Respiratory viruses	Community-acquired infections
	Persistent *Pseudomonas, Burkholderia cepacia,* and *Aspergillus* infections	Persistence of organisms from cystic fibrosis in the proximal airways and sinuses
	Opportunistic infections:	Patients receiving continuous high-level immunosuppression or therapy for steroid-resistant rejection, CMV infection
	Pneumocystis jiroveci	
	Cryptococcosis	
	Nontuberculous mycobacteria	
	EBV/PTLD	
	Herpes zoster	

CMV, cytomegalovirus; *EBV,* Epstein-Barr virus; *HHV,* human herpesvirus; *HSV,* herpes simplex virus; *PTLD,* posttransplant lymphoproliferative disease.

Modified from Rubin RH, Ikonen T, Gummert JF, Morris RE. The therapeutic prescription for the organ transplant recipient: the linkage of immunosuppression and antimicrobial strategies. *Transpl Infect Dis* 1999;**1**:39.

IMMUNOSUPPRESSION AND TIMING OF INFECTION

An understanding of the mechanisms and effects of immunosuppressive therapy is fundamental to anticipating the timing and types of infections that occur after transplantation, and several excellent reviews on these subjects are available.[135,576,580] The predictability of certain infections has facilitated establishing more timely diagnosis and determining strategies for preventive antimicrobial therapy.[212] Historically, the mainstay of immunosuppression has included corticosteroids and combinations of the following medications: azathioprine, the calcineurin inhibitors cyclosporine and tacrolimus, sirolimus, mycophenolate mofetil (MMF), and polyclonal and monoclonal antibodies. In recent years, substitution

TABLE 71-4 **Timing of Infections in 75 Pediatric Lung Transplant Recipients at Children's Hospital Los Angeles**

9-12	7

of MMF and tacrolimus for azathioprine and cyclosporine, respectively, has become standard and "corticosteroid-sparing therapy" also is gaining favor. Newer regimens may provide a superior cost-benefit ratio in terms of prevention of rejection, toxicity, and risk for infection.[135] A general time line of the occurrence of specific infectious agents in pediatric lung transplant recipients is presented in Table 71-4.

OVERVIEW OF INFECTIONS AND ANTIBIOTIC USE IN SOLID-ORGAN TRANSPLANTATION

The "therapeutic prescription," as described by Rubin and colleagues,[580] for successful organ transplantation requires a careful balance between immunosuppression and the use of antimicrobial agents therapeutically, prophylactically, or preemptively to manage the risk for rejection versus infection. A transplant recipient's risk for developing infection is determined by multiple factors, including (1) the technical skill of the surgeon; (2) the quality of perioperative care; (3) the "net state of immunosuppression"; (4) the patient's infectious exposure, including that from the community (past and present), hospital, and donor grafts; (5) the underlying condition of the patient (e.g., microbial colonization, organ dysfunction); and (6) the virulence of the organisms. Preventive/prophylactic strategies can alter these patterns, most notably for CMV and fungal infections, and delay their appearance past the expected time periods.[577] In sum, these considerations indicate that although a standard set of antimicrobial agents can be prescribed, they must be tailored closely to the risks, exposure, and immunosuppression of each individual.[581]

General principles of infection and therapy have been proposed by Rubin and Marty[581] and include the recognition that a transplant recipient is likely to have a greater microbial load and more advanced infection at the time of diagnosis, requiring longer therapy with greater potential for drug toxicity. Early establishment of the diagnosis and provision of therapy are paramount to a successful outcome. Furthermore, a broader range of organisms must be considered. Although a common practice in medicine is to assume a single diagnosis for a given manifestation, a recognized caveat is that transplant recipients may have "simultaneous and sequential" infections. In fact, many infectious processes are influenced directly by proceeding or concurrent events. The prototype of this interaction is the immunomodulating effect of CMV infection such that alterations in the cytokine/chemokine milieu, T-lymphocyte subsets and function, neutrophil activity, and activation of endothelial cells emerge. The result of these derangements is further immunosuppression, enhanced production of virus, and subsequent increased susceptibility to additional infections. Other putative immunomodulating viruses include human herpesvirus–6 (HHV-6), Epstein-Barr virus (EBV), and the hepatitis viruses.[581,613]

Length of therapy depends on consideration of the degree of current immunosuppression and location of the infection. In general, experts suggest that treatment be continued until all signs and symptoms of infection are gone, followed by a "buffer period" of weeks to months, depending on the infection,[581] but controlled trials on specific length of therapy for most infections are not available. Finally, drug interactions and toxicities, which may be synergistic, must be taken into consideration when prescribing medications for these patients.[440,580]

SITES OF INFECTION

Thoracic Cavity: Respiratory Tract Infections, Including Pneumonia and Anastomotic Site Infections

The vast majority, up to 80 percent, of infections in lung transplant recipients occur in the thorax-lung, mediastinum, and pleural space,[222] largely presenting as pneumonia.[9,17] In the CHLA cohort of patients during the first 12 months after transplantation, 62 percent of all infections consisted of pneumonia.[394] Organisms most frequently recovered include *Pseudomonas aeruginosa*, CMV, *Candida*, and *Aspergillus*, reflecting the high percentage of patients with CF in the transplant population. The onset of pneumonia in lung transplant recipients appears in a bimodal pattern, with most cases occurring in the first postoperative month. A second, albeit smaller group has late (6 to 12 months) recurrent episodes of gram-negative pneumonia associated with a poor outcome. The immunologic consequences of these infections in some patients may include bronchiolitis obliterans with organizing pneumonia (BOOP), which is characterized by inflammation and fibrotic granulation tissue of the small airways extending into the alveoli. The mortality rate of patients with BOOP is high (50%), and those who survive appear to be at an increased risk for developing bronchiolitis obliterans syndrome (41%).[17,118,222,246]

Unique to lung transplantation are bronchial anastomotic infections, most of which are fungal and caused by *Aspergillus* and *Candida*.[268,291,362,497,521] The bronchial anastomosis is susceptible to such infections for a variety of reasons. Anatomically, the posttransplant bronchus is relatively devascularized, with the blood supply flowing retrograde from the pulmonary arterial circulation. Neovascularization from collateral vessels takes as long as 1

month to occur, and, in the interim, the bronchus may experience ischemia and subsequent necrosis and sloughing of bronchial epithelium. Evolving surgical techniques have diminished this risk for ischemia in recent years. This environment is optimal for developing infection caused by saprophytic flora, such as *Aspergillus*, present in ambient air to which the airways are in direct contact. In addition, local reaction to suture material, postoperative corticosteroid use, and immunosuppressive therapy have a negative impact on healing and increase the patient's susceptibility to infection. As a result of this early tenuous anatomy, infections at this site are most likely to occur within the first 2 to 3 months after surgery.[127,268,291,499] Bronchial anastomotic infections rarely can lead to early catastrophic complications, such as dehiscence and hemorrhage. They are linked to substantial late bronchial complications, including dehiscence, bronchial stenosis, malacia, and retransplantation.[482,497]

Although some studies have demonstrated that pretransplant isolation of *Aspergillus* spp. has not been found to be a risk factor for the development of *Aspergillus* infection after transplantation,[335,499,529] others suggest that patients with CF and perioperative *Aspergillus* colonization may be at heightened risk for the development of early bronchial anastomotic infection. Although the numbers are small, the authors speculate that the presence of *Aspergillus* at the site of the fresh, devascularized anastomosis renders it more vulnerable.[499] Postoperative isolation of *Aspergillus* from airways appears to identify patients at risk for the later development of bronchial anastomotic abnormalities.[127,293,484,499] The overall incidence of airway infections and/or complications ranges from 5 to 25 percent.[127,268,293,482,497] The mortality rate associated with bronchial anastomotic infection and its complications is reported to be 2 to 7 percent.[291,497] Finally, one small study evaluating the effect of early sirolimus-based immunosuppression on the rate of rejection described poor wound healing and anastomotic complications in an unexpectedly high number of patients treated with sirolimus, which resulted in changes in immunosuppression strategies at that institution.[261]

A 2010 ISHLT consensus statement has formulated standardization of thoracic site infections in cardiothoracic transplant recipients, including pneumonia, tracheobronchitis, bronchial anastomotic infections, and viral/CMV and fungal respiratory tract infections.[314] The use of standard definitions going forward will better define the epidemiology of these infections and advance the quality of research aimed at therapeutic and prophylactic interventions.

Bloodstream Infections

The second most common site of infection is the bloodstream. Data are emerging regarding the epidemiology of bloodstream infections in pediatric and adult lung transplant recipients.[158,311,517] Bloodstream infections occur in 12 to 26 percent of transplant recipients, with staphylococci, *Pseudomonas aeruginosa*, and *Candida* spp. being the most common organisms identified. Late infections consist of a wide range of gram-negative organisms. Posttransplant bloodstream infections, especially early (<30 days) infection in children and candidal infection in both populations, were associated significantly with mortality. Infections may be related to pulmonary or vascular sites. In the pediatric population, most bloodstream infections were related to central venous catheters and were not secondary to other sites of infection (5% with pneumonia, sternal wound, ruptured subglottic cysts). These infections were most likely to occur in the first 7 days after transplantation. In adult transplant recipients, bloodstream infections largely were associated with pulmonary infections. Specifically, *P. aeruginosa* bacteremia was more likely to develop in adult patients with CF (20% of the transplant cohort) than in patients with other indications for transplantation. In this study, bloodstream infections with *Burkholderia cepacia* and *Staphylococcus aureus* were seen in similar frequency in non-CF patients, the former possibly related to a nosocomial outbreak.[517] In addition, bloodstream infections in patients with CF were associated with a decreased risk for death when compared with other lung transplant recipients with similar infections, possibly because antimicrobial agents active against resistant gram-negative organisms were being administered at the time that the infection developed. In children, *Pseudomonas* bloodstream infection was not associated with the diagnosis of CF (45% of the transplant cohort), nor with any outcome measures in this study. There exists an increasing concern for the impact of multidrug-resistant organisms, which were recovered in 57 percent of gram-negative–resistant bacteremias in one study (see later discussion).[311]

Empirical therapy in patients with suspected bloodstream infections should include agents active against staphylococcal and *Pseudomonas* spp. and be based on the patient's previous microbiologic findings, with a low threshold for adding antifungal therapy. Furthermore, the need for indwelling central catheters should be assessed routinely and catheters should be removed as soon as clinically feasible.

SELECTED PATHOGENS

Bacteria

Pseudomonas aeruginosa *and* Burkholderia cepacia *Complex*

P. aeruginosa and *B. cepacia* play prominent roles in postoperative infections in patients with CF. Despite the removal of colonized lung tissue with the procedure, the proximal airways and sinuses remain colonized and a source of infection postoperatively in immunosuppressed transplant recipients.[425] In patients with multidrug-resistant organisms this concern is heightened. Gram-negative multidrug-resistant organisms have been defined as those resistant to all agents in two or more classes of effective drugs[587] (e.g., resistance to all aminoglycosides, β-lactams, fluoroquinolones). *B. cepacia* complex organisms are resistant to aminoglycosides intrinsically, having high rates of resistance to β-lactams, inducible resistance to fluoroquinolones, and resistance to colistin and polymyxin.[93] In addition, these bacteria exist in a biofilm in

the airways of patients with CF, which greatly decreases therapeutic efficacy.[144,629]

As lung transplantation was emerging as a treatment option, patients infected with multidrug-resistant organisms generally were excluded.[499] Such decisions were based on data suggesting that pretransplant infection with multidrug-resistant *P. aeruginosa* and *B. cepacia* complex diminished the chance of survival and, therefore, was considered a contraindication to transplantation.[356,426,634] More recent data have documented that the presence of preoperative multidrug-resistant *P. aeruginosa* may not have an impact on survival; these patients may be more likely to acquire postoperative infections, but they generally respond to treatment without increases in short-term mortality rates, as recorded in the United Network for Organ Sharing (UNOS) database, so as not to prohibit transplantation.* The most recent ISHLT guidelines for selection of lung transplant recipients list "colonization with highly resistant or highly virulent bacteria, fungi, or mycobacteria" as a relative contraindication.[510] Additionally, these guidelines acknowledge that although "certain resistant pathogens may increase risk for poor outcome … it is not possible currently to identify absolute contraindications based on either the type of organisms or the pattern of antibiotic resistance." Despite the status of the immunocompromised host, the relatively low virulence of some of these organisms, the new healthy lung epithelium and improved airway function of the transplanted lungs, the aggressive use of antimicrobial agents during and after the procedure, and discordance between in vitro susceptibilities and in vivo efficacy may account for the diminished influence that multidrug-resistant pseudomonads have on the outcomes of transplant recipients.[510]

B. cepacia complex represents a group of nine related species that possess variable pathogenic potential in abnormal hosts.[397,398] Misidentification of *B. cepacia* complex organisms at the genus (*Alcaligenes*, *Stenotrophomonas*, and *Pseudomonas* most commonly) and species levels can occur.[397,447] This information is critical to evaluating patients considering transplantation and, in postoperative care, to assessing their risk for developing invasive disease.[397] There are species-specific differences in antimicrobial resistance and virulence. Several putative virulence/transmissibility factors that have been identified for *B. cenocepacia* (formerly genomovar III, ET-12 strain)[397] include quorum sensing,[636] cable pili (*cbl*A) for enhanced binding to respiratory epithelium,[589] increased neutrophil recruitment with suboptimal activation of polymorphonuclear neutrophils and macrophages,[588] and production of exopolysaccharides that inhibit neutrophil chemotaxis and scavenge reactive oxygen species.[97]

In the United States there has been a decline in *B. cepacia* complex in the CF population, from 3.6 percent in 1995 to 2.5 percent in 2010.[150,560] In Canada, this decline has also been documented from 15 percent, and as many as 80 percent involving *B. cenocepacia/genomovar III*,[174] to 4.6 percent in 2010.[105] This reassuring decrease in *B. cepacia* organisms is likely multifactorial, reflecting better microbiologic techniques for identification and infection control practices.[560] Controversy continues regarding performing transplantation on patients who harbor *B. cenocepacia*. Data demonstrate increased morbidity and mortality rates associated with this organism in nontransplanted patients with CF, including the occurrence of fatal cepacia syndrome.[323,331,380,381,424] Multiple studies of lung transplant recipients demonstrate an increase in mortality associated with *B. cenocepacia*, including late deaths as a result of infection associated with bronchiolitis obliterans syndrome and possibly *Burkholderia gladiola* but no other *Burkholderia* spp. It remains a contraindication for transplantation in some centers,* although successful transplantation has been accomplished with aggressive multidrug antimicrobial therapy, perhaps guided by multiple combination bactericidal testing, and a reduction in immunosuppressive therapy.[119,174,394,483]

Optimal therapy for infections due to multidrug-resistant *Pseudomonas* and *Burkholderia* spp. is not known. Therapy should be tailored to susceptibility studies, although in vitro susceptibilities may not correlate with in vivo activity and outcome.[631] In vitro synergy or multiple combination bactericidal testing for multidrug-resistant or pan-resistant gram-negative organisms can identify combinations of antimicrobial agents that inhibit bacterial growth and may facilitate the use of effective multidrug regimens.[1,2,93,373,587] A biofilm grown model of in vitro multiple combination bactericidal testing may better inform our therapeutic choices for these multidrug-resistant organisms and has identified a combination of high-dose tobramycin (inhaled), plus meropenem and a third antimicrobial agent (piperacillin/tazobactam, sulfamethoxazole/trimethoprim, amikacin, or ceftazidime) that inhibited the growth of most isolates.[151] How these data translate to patient care, however, has yet to be fully demonstrated. Published data did not reveal better outcomes, specifically the time to the next exacerbation, when using combination therapy to treat CF patients.[2] In this report, study patients received two-drug combinations based on multiple combination bactericidal testing, but these patients did not necessarily have multidrug-resistant/pan-resistant organisms, nor had they failed conventional therapy. Extrapolating these results to lung transplant recipients with multidrug-resistant organisms is difficult. The CHLA transplant team has been using multiple combination bactericidal testing from the University of Ottawa since 2001; our experience suggests that this approach, with three or four drugs used in combination, is helpful for managing preoperative and postoperative patients with multidrug-resistant/pan-resistant organisms, including *B. cepacia* complex.[394] Clearly, additional data are needed to assess this approach for lung transplant recipients infected with multidrug-resistant organisms.

For lung transplant recipients with susceptible *P. aeruginosa* infection, combination therapy is recommended, including an extended-spectrum, antipseudomonal β-lactam and an aminoglycoside, if renal status allows. For *B. cepacia* complex, combinations that include ceftazidime, meropenem, TMP-SMX, tetracyclines, quinolones, and

*References 34, 182, 214, 269, 335, 498.

*References 14, 35, 75, 119, 173, 175, 397, 479, 483.

even chloramphenicol have been used.[317] Aerosolized antibiotics (tobramycin, colistin, or aztreonam) can deliver drug levels above the minimal inhibitory concentrations of resistant organisms directly to the lungs and thereby reduce the bacterial burden with minimal systemic toxicity.[205,235,239,456] As a rule, aerosolized antibiotics should not be used as single therapy for infection in lung transplant recipients, who are at risk for dissemination. A prophylactic protocol utilizing aerosolized aztreonam has been employed at CHLA.[739] Therapy is initiated in patients identified with *B. cepacia* complex, preoperatively if possible, and continued through the first year after transplantation. Preliminary data suggest that outcomes are similar to those of patients who are colonized with susceptible *Pseudomonas* organisms. Further investigation is needed in this promising area of therapy. Colistin aerosols may also be useful for the treatment of pan-resistant organisms.[39,53] Although historically, renal toxicity often precluded its systemic use, recent studies suggest that intravenous colistin can be used successfully as well.[152,202,213] Finally, strategies that employ extended or continuous infusions of β-lactam antibiotics may optimize the pharmacokinetic/pharmacodynamic properties of these drugs and may improve outcome.[466,472,566] The duration of therapy requires individualization but generally is not less than 2 weeks, and treatment should be continued for a significant period after the signs and symptoms of infection have resolved.

β-*Lactamase–Producing Multidrug-Drug Resistant Organisms (Enterobacteriaceae,* Acinetobacter*)*

Multidrug-resistant, β-lactamase–producing Enterobacteriaceae *(Klebsiella pneumoniae*, *Escherichia coli)* and *Acinetobacter baumannii* are being increasingly recognized as causes of infection worldwide; as many as 1000 β-lactamases have been identified, including cephalosporinases extended-spectrum β-lactamases (ESBL), K. pneumonia carbapenemases (KPC) , AmpC β-lactamases, and metallo β-lactamases (MBL), rendering them resistant to a wide range of β-lactamase antimicrobial agents.[427,434,683] The extent of their impact on transplant recipients in general and in pediatric lung transplant recipients is unknown and limited to case reports and small surveys, mostly in adult transplant populations,[36,58,532] but has been described in pediatric liver or intestinal transplantation and, notably, in outbreak situations.[250,561] Infections may originate from the recipient or donor.[242,437] Increased risk related to antimicrobial exposure, infection control practices, invasive procedures, and prolonged hospitalization, especially associated with intensive care units, is likely.[476] Carbapenems (meropenem, imipenem) are generally considered the drugs of choice for extended-spectrum β-lactamase–producing organisms, especially for empirical therapy,[427,736] although β-lactam/β-lactam inhibitor combinations may be appropriate based on in vitro susceptibilities, especially at high doses.[537,568] Carbapenemase-producing organisms provide additional challenges to therapy, because the number of available effective agents is limited and few new options are in development; therapy should be guided by susceptibilities and perhaps multiple combination bactericidal testing. Drug combinations including colistin, tigecycline, doripenem, and ceftobiprole may be considered.[329,434,532,683] The transplant community continues to discuss the implications these organisms may have on transplant recipient and donor candidacy.[608]

Mycobacterium tuberculosis

Worldwide, *Mycobacterium tuberculosis* (MTB) remains an important pathogen in solid-organ transplant recipients, and the rate of infection is associated with the endemicity of infection. As noted by many authors, MTB behaves as an opportunistic infection in these patients in that its frequency in solid-organ transplant recipients is greatly increased in comparison with the normal population (up to 74-fold) and presents as diverse manifestations, including high rates of extrapulmonary disease and increased mortality rates.* Most cases of infection with MTB in adult transplant recipients arise from reactivation of latent infection from recipient or donor; acquired cases are seen, especially in pediatric patients.[91,445,470,690] Multiple cases of donor-derived MTB infection, including pulmonary MTB infection in lung transplant recipients[565] and extrapulmonary MTB infection in renal and liver transplant patients, have been documented.[248,565,737] In addition, nosocomial transmission to transplant recipients has occurred.[328]

Among solid-organ transplant recipients, MTB infections occur most frequently after lung transplants (1% to 6.5%).[626,675] Studies of MTB infection in solid-organ transplant recipients, including small numbers of children, suggest that most cases occur within the first post-transplant year, with a median time of 9 months for all solid-organ transplant recipients and 3.5 months for lung transplant recipients. Risk factors for MTB infection include allograft rejection; receipt of OKT3 or anti–T-cell antibodies, which also predict dissemination; previous exposure to MTB, with radiographic evidence of old infection or a history of a positive tuberculin skin test; renal failure/hemodialysis; liver disease; diabetes mellitus; and older age.[91,675] Coinfection with CMV, mycoses, *Pneumocystis jiroveci*, and *Nocardia* has been associated with the development of disease.[470,477] As would be expected, most manifestations include pulmonary disease (>70%), with interstitial infiltrates, nodules, effusion, and cavities seen on imaging studies.[626,675] Presentations with extrapulmonary disease (15%) involve the gastrointestinal tract, skin, musculoskeletal system, genitourinary system, lymph nodes, and central nervous system (CNS). Disseminated disease has been demonstrated in up to a third of patients, 91 percent of whom were febrile as compared with 64 percent of those with localized disease.[626] Attributable mortality from MTB infection in solid-organ transplant recipients is reported to be 9.5 to 29 percent. Significant predictors of mortality are disseminated disease, previous rejection, and receipt of OKT3 or anti–T-cell antibodies.[626]

Several studies have investigated mycobacterial infections specifically in lung transplant recipients.[81,340,428,470] Two of the studies were conducted in regions with a low

*References 91, 477, 578, 626, 656, 675.

endemicity of MTB infection—Australia and North America (affecting 5 to 15/100,000 population)—and two in Spain (25 to 49/100,000 population). Rates of MTB infection in lung transplant recipients in the two former studies were less than 1 percent, although still well above the national average,[340,428] but they were 2.6 percent and 6.4 percent (500-fold higher than the national average) in the Spanish studies.[81,470] Indeed, nontuberculous mycobacterial infections were more common than were MTB infections in the first two reports, whereas nontuberculous mycobacterial infection was encountered only once in the Spanish study. Mortality ranged from 0 to 43 percent.[81,340,470,626]

Few data exist on MTB infections in pediatric solid-organ transplant recipients, and none exist in lung transplant recipients. Although children have an age-related, lower accumulated risk for being infected, even immunocompetent children with MTB infection are more likely to have progression to dissemination and mortality, especially those younger than 5 years of age and during adolescence.[147] This pattern appears to be mirrored in the transplant population. Small, published series of MTB infection in solid-organ transplant recipients most often describe fever and pulmonary findings, with high rates of dissemination (50%); mortality ranged from 0 to 30 percent.[91,445,687,690] Pediatric patients presented later after transplant than adults (median of 8 months vs. 4 months) as a result of differences in acquisition of disease. Tuberculin skin test results were negative or minimal in all patients. Furthermore, screening of family members was very useful in both series of pediatric patients, thus suggesting that, as for immunocompetent children, the index case of exposure is in the home. Invasive diagnostic procedures were needed to confirm the diagnosis in many patients. An additional case report of MTB complex disease in a pediatric renal transplant recipient highlights another potential difference between pediatric and adult cases.[124] *Mycobacterium bovis* disease, which can be indistinguishable from MTB infection but often presents as abdominal disease, developed in this child. It is usually acquired from the ingestion of unpasteurized milk products from infected cows. It appears to be distinctly more common in children and, in the United States, is seen most often in children who have immigrated from or visited countries where *M. bovis* is endemic in cattle, such as Mexico.[154] The importance of recognizing this infection is its inherent resistance to pyrazinamide and the implications for therapy.

A screening risk assessment with history, including exposures, travel, receipt of bacille Calmette-Guérin (BCG) vaccine, and physical examination, as well as performing a tuberculin skin test should be documented in all pediatric transplant candidates.[91,656] A 5-mm induration should be considered positive in an immunocompromised child, because positive results require intact T-cell function; false-negative results may be secondary to nutritional status, organ failure, or medication-related immunodeficient states.[28,91] Screening of household contacts should also be considered. Interferon-gamma (IFN-γ) release assays have emerged as valuable tools for the screening/diagnosis of latent tuberculosis infection and include the "QuantiFERON-TB Gold (QFT-G) and in tube" (QFT-GIT), a whole-blood enzyme-linked immunosorbent assay (ELISA), and "T-SPOT.TB," an ex-vivo enzyme-linked immunospot (ELISpot) assay.[442,443,563,597] Both assays rely on interferon production from peripheral blood mononuclear cells in response to specific MTB antigens. The advantage of these tests is the discrimination of MTB from nontuberculous mycobacterial infections, as well as BCG vaccine response. These tests have higher specificity than the tuberculin skin test, especially with regard to the BCG vaccine, and may be most useful in low-endemic, high-resource settings.[442,514,644] In addition, positive and negative controls allow for better assessment of anergic responses. Clear differences in the sensitivities of the tuberculin skin test and the available IFN-γ release assays are difficult to demonstrate.[443,516,551] The T-SPOT.TB may be more sensitive in immunocompromised patients.[443,551,564] However, the use of IFN-γ release assays in young children (<5 years) and immunocompromised patients is still being evaluated.* The use of both the tuberculin skin test and the IFN-γ release assays may increase the sensitivity of detection of infection, because discordant results in children and immunocompromised populations have been well documented.[6,91]

Diagnosis of active MTB infection in the transplant setting can be challenging because symptoms may be nonspecific, such as fever of unknown origin, or unusual, such as abdominal manifestations; coinfections may also modify the signs and symptoms, and immune response–based diagnostic methods lack sensitivity. Consequently, a high index of suspicion is required, and, frequently, aggressive diagnostic techniques, such as bronchoscopy, laparoscopy, and tissue biopsy, are needed.[445,690] The American Thoracic Society and the Centers for Disease Control and Prevention (CDC) have published recommendations for diagnosis of MTB disease.[29,108,597] Several new methods are available for culture-based diagnosis. Broth-based culture systems coupled with DNA probes allow more rapid establishment of a diagnosis.[515,597] Two commercially available kits are available in the United States for diagnosis based on nucleic acid amplification assays.[515] They are approved for smear-positive and smear-negative samples and may provide results within 24 to 48 hours. Although there is still some debate on the optimal use of these tests, CDC guidelines state that nucleic acid amplification assays should be performed on at least one specimen for all patients in whom the diagnosis of tuberculosis is being considered but not established.[110] Although culture-based, indirect diagnostics are the most widely available methods by which to assess susceptibility, these methods have long turnaround times. Technologies for the rapid detection of multidrug-resistant organisms are evolving.[38,597,669] Newer modalities such as the microscopic-observation drug susceptibility, nitrate reductase assay, and molecular methods such as GenoType MTBDR assays may allow rapid, inexpensive diagnosis and susceptibility testing even in countries with limited resources.[96,113,322,469,515]

Because pediatric lung transplant recipients are at heightened risk for development of progressive

*References 414, 443, 514, 551, 564, 644, 670.

tuberculous infection, expert opinion supports the use of 9 months of isoniazid (INH) chemoprophylaxis for pediatric candidates or recipients with latent tuberculosis. The morbidity and mortality from MTB is high enough to warrant the risk for potential hepatotoxicity in most cases, unless severe liver disease is also present.[91,477,626,656] Rifampin alone may also be an acceptable regimen, although drug-drug interactions are common (see later discussion).[656] Completing therapy prior to transplant is optimal, but it can be accomplished after transplantation. An alternative strategy is active surveillance, with initiation of INH only if additional risk factors are present, such as recent conversion, exposure to active MTB, a recipient or donor with a history of MTB infection without adequate therapy, or the existence of significant abnormalities on chest radiographs.[578] All family and close contacts with latent or active tuberculosis should also be treated.[91]

Optimal therapy for pediatric lung transplant recipients with active tuberculosis has not been defined, but an empirical multidrug regimen such as those recommended for active disease in other populations, modified by susceptibilities as necessary, should be initiated.[25,71,656] Complicating factors include liver toxicity and drug interactions. INH, especially in combination with other first-line drugs, such as rifampin and pyrazinamide, can lead to toxicity, requiring discontinuation of all or some of these drugs and the need to institute new regimens.[477,626] Drug toxicity is most notable in adult liver transplant recipients. Liver biopsy may be necessary to distinguish drug toxicity from rejection or hepatic granuloma from MTB infection.[477,578,626] Pediatric patients generally tolerate first-line therapy, with occasional need for reduced dosage and rarely discontinuation.[25,71,124,690] For patients with suspect or proven multidrug-resistant tuberculosis, close consultation with public health services and specialists in treating this disease should be employed for optimal management.

The use of rifampin in solid-organ transplant recipients deserves special comment. Although rifampin-containing regimens may portend the best microbiologic outcome, significant morbidity from graft dysfunction and loss can be due to the simultaneous use of rifampin with immunosuppressant agents. Rifampin lowers serum levels of cyclosporine and tacrolimus considerably, as well as decreases corticosteroid levels somewhat, via induction of cytochrome P-450.[183] Current recommendations suggest that rifampin can be used successfully with increased calcineurin inhibitor dosing and careful monitoring of calcineurin inhibitor serum levels.[428,690] Rifabutin may offer equivalent efficacy with less effect on drug interactions, as has been documented in tuberculosis/human immunodeficiency virus (HIV)–coinfected individuals on antiretroviral therapy.[91,109,656] Others suggest that a longer duration of therapy (up to 50%) with rifampin-free/INH-containing regimens has a comparable outcome without the risk for rejection and potential graft loss.[81,477] Most authors agree that regimens should contain INH if at all possible.* If rifampin-free regimens are used, therapy should be prolonged to a minimum of 12 to 18 months.[81,626] Ethambutol and second-line therapies (aminoglycosides and quinolones) may be considered if a first-line drug cannot be used.[477,578] If both INH and rifampin are not used, because of toxicity, drug interactions, or resistance, therapy should be continued for a prolonged period, possibly 2 to 3 years.[91,578]

Nontuberculous Mycobacterial Infections

Nontuberculous mycobacterial infections are more common in lung transplant recipients than MTB infections, in areas where MTB is not endemic, including the United States.[189] There are currently more than 125 species of nontuberculous mycobacterial organisms; recent advances in molecular methods of taxonomy have better informed our understanding of the epidemiology, outcome, and treatment of these different species.[258] The clinically relevant species are divided into slowly growing species—*Mycobacterium avium* complex (MAC), *Mycobacterium kansasii*, *Mycobacterium marinum*, and *Mycobacterium ulcerans*—and rapid growers—*Mycobacterium fortuitum* group, *Mycobacterium chelonae*, and *Mycobacterium abscessus*.[26] *M. abscessus* has now been subdivided as well into *M. abscessus* subsp. *abscessus*, *M. abscessus* subsp. *bolletii*, and a third subspecies awaiting further taxonomic clarification.[256] Patients with chronic lung disease and CF in particular have a high incidence of nontuberculous mycobacterial colonization. More recent data suggest that 6 to 24 percent of patients with CF are colonized with nontuberculous mycobacterial organisms, most commonly *M. abscessus* or MAC.* The contribution of these organisms to progression of lung disease in pretransplant patients is still being defined,† but the impact on the lung transplant recipient, especially from infections due to *M. abscessus*, deserves emphasis.

Clinical manifestations of nontuberculous mycobacterial infection in lung transplantation vary by organism and include pulmonary, surgical site infections, and cutaneous and disseminated disease.[189] In a survey of 31 transplant centers regarding *M. abscessus* infection in lung transplant recipients, 17 patients were identified (0.33%).[125] The majority had pulmonary infections, followed by skin involvement; several patients had both. Disease occurred at a median of 18.5 months after transplantation (1 to 111 months). Only 2 were preoperatively colonized. Pulmonary disease may be manifested as chronic cough, sputum production, and fatigue. Skin infections may involve surgical sites (sternal wounds) and extremities.[115,428] Painful, erythematous cutaneous or subcutaneous nodules may develop into abscesses and ulcerate.[125] In two additional single-center retrospective studies involving adult lung transplant recipients, most of whom underwent transplants because of chronic obstructive pulmonary disease, the rate of posttransplant nontuberculous mycobacterial infection was approximately 20 percent, with progression to disease in 25 percent (pulmonary infection) and 11 percent (pulmonary and surgical site infections) of those colonized.[303,348] Nontuberculous mycobacterial infection, colonization, or disease was

*References 115, 201, 255, 389, 399, 505, 508, 546, 556, 610.
†References 149, 201, 253, 280, 505-507.

associated with increased mortality in one study, which showed with a higher rate of *M. abscessus* infection.[303] A study of end-stage CF patients referred for transplantation revealed 20 percent of patients were colonized with nontuberculous mycobacterial organisms (equal numbers of MAC and *M. abscessus*); after the transplant, nontuberculous mycobacteria were isolated from 14 percent of CF lung transplant recipients. The prevalence of posttransplant invasive disease was approximately 3 percent (25% of those colonized), in both pulmonary and surgical site infections, the majority being caused by *M. abscessus*.[115] Pretransplant colonization with *M. abscessus* was associated with posttransplant disease. All patients in this series who were ill from infection with this organism were successfully treated. Emerging data support the association between preoperative colonization and posttransplant infections with *M. abscessus* and document rare, yet serious and sometimes fatal posttransplant infections.*

Diagnosis requires a high level of suspicion. Cutaneous lesions should be sampled for histology, special stains, and culture. The differential diagnosis includes fungal and nocardial infections. These organisms are ubiquitous, and differentiating respiratory tract colonization from infection may be difficult. The diagnosis of nontuberculous mycobacterial infection should be entertained, with a low threshold for performing bronchoalveolar lavage (BAL) or biopsy for any unexplained or unresolving pleuropulmonary disease.[189,258] The American Thoracic Society/Infectious Diseases Society of America (ATS/IDSA) has published diagnostic criteria that include signs and symptoms present after the treatment of other possible diseases, such as radiologic evidence of progressive pulmonary disease, including infiltrates, cavities, nodules, or bronchiectasis, and bacteriologic evidence of nontuberculous mycobacterial infection, generally on multiple respiratory or biopsy specimens.[158]

Providing therapy for nontuberculous mycobacterial infection may be difficult, depends on the species isolated, and should be determined in consultation with experts and with adherence to the ATS/IDSA guidelines.[258] Despite the use of seemingly adequate therapy, failures and recurrences are common.[256-258] Therapy for infection with MAC includes a macrolide, ethambutol, and rifampin, with or without an aminoglycoside, depending on the severity of disease. Susceptibility to macrolides should be performed; it is the only class of drug for MAC in which there is evidence to support an in vitro and in vivo response.[256,258] Therapy for infection with *M. abscessus* is undefined because this organism is notoriously resistant to many antimicrobial agents. Even regimens based on in vitro susceptibilities may not produce a cure, which may be in part explained by the discovery of the presence of an inducible macrolide resistance gene *erm(41)* in many clinical isolates, which can produce in vivo resistance despite demonstration of susceptible minimal inhibitory concentrations.[484] Combinations that include a macrolide, amikacin, and cefoxitin or a carbapenem, based on susceptibility testing, are general recommendations. Acquired resistance mutations to clarithromycin and amikacin can occur.[258] The duration of therapy is prolonged and depends on the patient's clinical, radiologic, and microbiologic response, but the suggested minimum duration is 12 to 18 months. Reduction of immunosuppression, surgical excision or débridement, and treatment of coinfections may improve the outcome.[125,256] Relapses are not uncommon. Consideration of lifelong suppression is recommended by some experts for patients with a high burden of disease and persistently high levels of immunosuppression.[109] Most patients who can complete long-term therapy improve (32% cleared their infection, 36% improved); minimal response to therapy was seen in 23 percent of lung transplant recipients.[196] Fatal infections occur rarely.[125,591,667] Drug interactions between macrolides and rifampin and between calcineurin inhibitors and sirolimus occur. Both can lower serum levels of immunosuppressive drugs and trigger rejection.

Most centers do not consider the presence of nontuberculous mycobacterial infection an exclusion to transplantation, although the optimal management of these patients is debated. Clearly, patients often remain colonized in respiratory tree sites above the anastomosis. The hilar lymph nodes in two patients were positive for *M. abscessus*, thus suggesting other potential reservoirs.[115] Given the concern for emergence of resistance toxicity and drug-drug interactions related to long-term therapy, prolonged antimycobacterial therapy cannot be recommended for all patients. Some centers opt for pretransplant or peritransplant prophylaxis, whereas others recommend observation for evidence of disease.[189]

Fungal Infections

Aspergillus

Aspergillus infections remain a major challenge to the success of lung transplantation. Most common presentations involve the respiratory tree (up to 90%), with manifestations ranging from semi-invasive tracheobronchitis and bronchial anastomotic infections to invasive pulmonary disease and, rarely, dissemination to extrapulmonary sites, including the CNS (10%).[232,619] The published rates of invasive *Aspergillus* infections vary considerably and probably reflect differences in dates of publication, patient populations, underlying disease such as CF, net state of immunosuppression, use of prophylactic measures, local issues of exposure (e.g., construction), and rates of rejection and viral infection, among others. In addition, distinguishing between isolation of *Aspergillus* from airway cultures versus true invasive disease may be difficult. Despite these caveats, rates of invasive *Aspergillus* infection in lung transplant recipients are the highest among solid-organ transplant recipients. Studies suggest that invasive disease occurs in 3 to 33 percent of lung transplant recipients, although rates of colonization/isolation of *Aspergillus* may be considerably higher. In most cases, colonization appears to be transient and does not lead to invasive disease.*

*References 115, 125, 189, 340, 428, 591, 667, 744.

*References 98, 159, 232, 244, 288, 402, 448, 461, 467, 486, 499, 526, 619.

A bimodal pattern of the development of invasive *Aspergillus* infection in transplant recipients has been recognized. Most infections develop 1 to 6 months after transplantation and are a major cause of death during this time period,* but late infections longer than 1 year post transplant occur as well.[232,402,486,617] Infections that develop less than 3 months after transplantation are more likely to be tracheobronchitis or bronchial anastomosis site infections; patients who require retransplantation or have bronchial anastomotic infection may present in the first month.[127,268,291,461] Invasive pulmonary or disseminated aspergillosis may occur at any time.[159,402,486,619,637] Risk factors for early disease in lung transplant recipients include *Aspergillus* colonization in the 6 months before transplantation or early posttransplant colonization, a complicated postoperative period, A2 or repeated rejection, and CMV disease or receipt of CMV prophylaxis as a marker for donor/recipient seropositivity.† Corroboration of the importance of CMV is the observation that a significant decrease in invasive *Aspergillus* was associated with the use of prophylactic ganciclovir in heart transplant recipients, reflecting the immunomodulating effects of the virus on host immune status.[574,704] Adult patients in whom invasive *Aspergillus* infection developed later after transplantation were older and "overimmunosuppressed" secondary to chronic or refractory graft rejection or dysfunction.[232,621] In both the early and late groups, invasive *Aspergillus* was associated with renal failure and repeated bacterial infections.

Aspergillus fumigatus causes the majority of disease, although non–*A. fumigatus* species are becoming more common.[98,448] Such species include *Aspergillus flavus*, *Aspergillus niger*, *Aspergillus nodularis*, *Aspergillus ustus*, and *Aspergillus terreus*. Non–*A. fumigatus* species have a recognized potential for differences in antifungal susceptibility. For example, *A. terreus* is innately resistant to amphotericin B and *A. ustus* has diminished susceptibility to the azoles.[51]

Clinical findings in patients with pulmonary disease are largely nonspecific and may include cough, shortness of breath, and hypoxia, although chest pain and occasionally hemoptysis may raise clinical suspicion of infection with invasive *Aspergillus*.[165] Symptoms are seen more commonly in patients with diffuse disease than in those with focal or nodular disease. Although fever is a common early manifestation of infection with invasive *Aspergillus* in neutropenic patients with a hematologic disorder, it occurred in only 15 percent of lung transplant recipients with *Aspergillus* infection and usually more often in patients with disseminated (50%) or invasive pulmonary disease (20%) than in those with tracheobronchial or bronchial anastomotic infections (0%).[619] Lack of fever also has been documented in other studies of nonneutropenic patients with invasive *Aspergillus* infection. Patients with disseminated disease may have involvement of the sinuses, orbits, musculoskeletal system (osteomyelitis), ophthalmologic structures, cutaneous sites, and CNS. Symptoms of CNS disease may include headache, sinus pain, cranial nerve abnormalities, seizures, changes in mental status, or other focal neurologic findings.[51,165,244]

The radiologic manifestations of invasive *Aspergillus* infection in lung transplant recipients are highly variable.[165,178,606,673] Chest radiographs are insensitive and nonspecific. Computed tomography (CT) of the chest has become an integral part of early diagnostic strategies and has been incorporated into recent definitions of invasive fungal infections in immunocompromised hosts.[40,168] On chest CT scans of neutropenic adults, large nodules and cavitary lesions are common findings.[40,100,254] In addition, much has been made of the early "halo sign," a macronodule surrounded by a perimeter of "ground-glass" opacity (edema and hemorrhage), and the later "air crescent sign," a crescent-shaped air interface between viable lung and infarcted tissue at the periphery of a nodule that is seen with recovery and return of neutrophils. These findings are considered highly suggestive, although not pathognomonic, of invasive *Aspergillus* infection. Unfortunately, these findings are seen less commonly in lung transplant recipients and in children in general. Multiple ill-defined pulmonary nodules were the most common findings in adult lung transplant recipients, with approximately half demonstrating halo signs. Cavitation was rarely seen, and no air crescent signs were observed.[178] In children, radiographic findings were highly variable and included consolidations and small nodular masses and effusions, with little evidence of cavitation or halo or crescent signs.[92,673]

The gold standard for diagnosis of invasive *Aspergillus* infection is the demonstration of small hyaline, septate, dichotomously branched hyphae in tissue with evidence of associated tissue damage or positive cultures from a normally sterile body site, in the presence of signs and symptoms of invasive disease.[40,51,165,168,298] Blood cultures are rarely positive. Obtaining adequate tissue specimens in a timely manner frequently is not possible. An immunocompromised patient with neutropenia or who is on corticosteroid therapy may not exhibit obvious signs or symptoms of invasive disease until late in the course of infection.[15] Additionally, these patients are often deemed too ill to undergo the invasive procedures necessary to obtain tissue for microbiologic and histopathologic evaluation.[627] Therefore, the diagnosis is established late in the course of the disease or at autopsy. Indeed, frequently it is not established but is based on radiologic and host factors.

Early diagnosis is thought to be critical to improving the outcome of patients with invasive *Aspergillus* infection, especially now with the availability of more active therapeutic agents. In addition to early CT in high-risk patients, especially those who do not respond to broad-spectrum antibacterial therapy, there have been several recent advances in molecular/non–culture-based approaches to establishing a diagnosis. The most widely used and well characterized of these modalities is the Platelia *Aspergillus* serum galactomannan antigen, detected by double-sandwich ELISA.* This test detects very small amounts of a polysaccharide cell wall

*References 159, 362, 448, 461, 486, 619.
†References 98, 159, 232, 288, 321, 402, 467, 499, 617.

*References 451, 452, 654, 665, 722, 724.

component of *Aspergillus* and other fungal species released by invading hyphal elements. A repeated serum level of more than 0.5 is considered positive. This galactomannan antigen has been shown to be a useful tool for screening high-risk patients, triggering obtaining CT scans, thus establishing the probable diagnosis of invasive *Aspergillus* infection[95,420,569] and allowing for early therapy.[421-423,429] The use of this assay has been incorporated into the definitions for invasive fungal infections from the European Organization for Research and Treatment of Cancer/Invasive Fungal Infections Cooperative Group and the National Institute of Allergy and Infectious Diseases Mycoses Study Group (EORTC/MSG) consensus group.[40,168] It has also proved useful in measuring response to therapy, and correlations have been made with progressive disease seen with rising levels of galactomannan antigen and improved survival with decreasing levels.[112,416] It may also be informative if the diagnosis of immune reconstitution inflammatory syndrome (IRIS) is being considered (see later discussion).[267,454]

False-positive tests have been documented, notably in patients receiving piperacillin-tazobactam, which has been found to contain galactomannan antigen,* likely related to cross reactions to *Penicillium* spp.–derived semisynthetic penicillins.[655] More recent analysis for galactomannan antigen in patients receiving piperacillin-tazobactam and of vials of currently available brand piperacillin-tazobactam did not demonstrate this association.[457] In general, false-positive tests result in transient and low-positive values and may be differentiated from true-positive results, which tend to be repeatedly positive.[451,722] Initial pediatric data suggested that children had higher rates of false positivity[290,569,657]; more recent pediatric studies have not confirmed this observation.[37,208,301]

In solid-organ transplant recipients and nonneutropenic patients, galactomannan antigen testing of blood appears to be less sensitive for the detection of invasive *Aspergillus*.[215,313,372,543,691] In addition, antifungal therapy has been shown to decrease the sensitivity of the assay.[429,432,569] However, its use in BAL fluid may have a higher diagnostic yield and has been recently approved by the U.S. Food and Drug Administration (FDA) for this use.† Several studies in lung transplant recipients suggest that galactomannan antigen levels greater than 1.0 from BAL fluid evaluation have good sensitivity (60% to 100%) and specificity (90% to 98%) for determination of invasive *Aspergillus* infection.[273,312,316,531] Galactomannan antigen values between 0.5 and 1.0 should be interpreted in clinical context.

The Fungitell (1→3)-β-D-glucan assay measures a cell wall component found in many fungi, including *Aspergillus* and *Candida* spp. and *Pneumocystis*, but like galactomannan antigen does not detect Zygomycetes.[338,465,500,512,535] It is approved by the FDA to aid in the diagnosis of invasive fungal infections and has been incorporated into the definitions for these infections.[168] Cross-reacting glucan-containing material occurs commonly in the environment, and false-positive tests have been demonstrated in dialysis patients, those exposed to gauze, and those with some gram-positive bacteremia. In addition, false-positive results are associated with the use of some antimicrobial agents and with sample manipulation, thus suggesting that laboratory contamination is possible.* A study in lung transplant recipients suggests it has a low positive predictive value, thus limiting it use as a screening tool, and false-positive findings occurred with mold colonization and hemodialysis. Unlike serum galactomannan antigen, it does not appear to correlate with response to therapy or have prognostic value, because it declines slowly, even with clinical improvement.[16,355]

The *Aspergillus* polymerase chain reaction (PCR) assay remains nonstandardized, but most assays rely on detection of fungal sequences (panfungal or genera/species specific) of 18S or 28S rRNA or mitochondrial genes in whole blood, plasma, serum, or BAL fluid. More recent protocols have used real-time PCR, which allows rapid, automated, quantitative, and reliable results, with less chance of contamination.† Optimization of nucleic acid extraction, design of primer pairs and probes, and patient sample site (e.g., blood, serum BAL fluid) as well as the development of newer techniques that can identify resistance genes are underway. [361] While clinical information is accumulating, standardization and validation from large studies remains lacking, although some studies suggest that PCR can detect *Aspergillus* before galactomannan antigen appears in blood and may be effective when applied to nonblood samples such as BAL fluid, CSF, and tissue.[495,630,729,731] Studies comparing the use of molecular methods of diagnosis are ongoing.‡ Several authors suggest that combining two methodologies may improve diagnostic sensitivity.§

Despite historically poor outcomes of invasive *Aspergillus* infection in immunocompromised patients, new mold-active therapies appear to be associated with improving mortality figures.[495,658,682] The Infectious Diseases Society of America (IDSA) practice guidelines for *Aspergillus* infections, published in 2008, recommends therapy with voriconazole as primary therapy for most patients, because it has demonstrated outcome superiority.[46,168,172,710] Additionally, voriconazole has shown promise for treatment of CNS disease, which historically has been uniformly fatal.[329,599,719] For patients refractory to or intolerant of primary therapy, lipid formulations of amphotericin B deoxycholate (AmBd), itraconazole, and caspofungin are FDA approved for treatment of invasive *Aspergillus* infection.

Data are now emerging on the use of voriconazole for invasive *Aspergillus* infection in pediatric patients and solid-organ transplant recipients. The optimal dosing for pediatric patients remains undefined at present but data suggest that much higher doses than currently recommended are tolerated and beneficial.¶ Several studies

support the importance of therapeutic drug monitoring of voriconazole as it relates to improved outcome, especially in children and other patient populations, including those with CF.[30,59,88,185,485,638] Reproducible data suggest trough levels between 1 and 5 μg/mL are correlated with improved outcome and decreased toxicity. Toxicities include hepatotoxicity and CNS and visual disturbances (photopsia) and are generally dose related and reversible, although fatal liver failure has been reported.* Cutaneous photosensitivity, which can be chronic, and the development of skin malignancies have also been documented but are likely related to duration of therapy and not serum levels.[60,146,751] Voriconazole is available in intravenous and oral formulations, which allow for transitioning to oral dosage when the patient's condition has improved and he or she can tolerate oral medication and is at home. However, there appear to be multiple factors that affect the "bioavailability," most notably in children, but also some adults and CF and other high-risk patients, such that therapeutic drug monitoring should be done before all oral dosing to evaluate absorption, food intake, and polymorphisms in metabolism of CYP2C19 P-450 enzyme.[30] Concern over potential renal toxicity associated with the accumulation of the intravenous solvent vehicle sulfobutylether-β-cyclodextrin, as seen in animal models, has led to a contraindication of the intravenous administration of voriconazole in patients with renal failure on standard renal replacement therapy.[3,270,487,703] This remains an area of investigation.

Several important drug interactions occur with medications routinely used in solid-organ transplant recipients. The most important of these interactions involves tacrolimus and sirolimus, in which concomitant use with voriconazole can lead to decreased metabolism, via cytochrome P-450, and result in greatly increased serum levels of the immunosuppressant.[582] The use of tacrolimus can be controlled safely by reducing the dose by 50 percent and monitoring daily levels.[582,688] The effect of voriconazole on sirolimus levels is even more pronounced, and it is labeled as an absolute contraindication by the manufacturer.[582,583] Several case reports and small series describe the use of these two drugs together, with significant dose reduction of sirolimus (up to 90%) and close follow-up of serum sirolimus levels.[438,441,583] The use of rifampin and voriconazole should be avoided if possible, because voriconazole levels may be significantly decreased in this setting.[234] Posaconazole, the newest and most broad-spectrum azole, with activity against many non-*Aspergillus* molds and Zygomycetes is recommended as an alternative for treatment of invasive *Aspergillus* infection in patients refractory or intolerant of other therapy, including voriconazole.[13,360,600,708,711] It is also licensed for prophylaxis in patients 13 years of age and older with fever and neutropenia or graft-versus-host disease.[139,679] Its safety and drug interaction profile is similar to that of voriconazole. On the other hand, optimal dosing remains an issue, especially in children for whom no specific dose recommendations exist,[718] and it is only available in oral formulation, which limits its utility in critically ill patients. Absorption is improved with fatty foods and lower stomach pH. Therapeutic drug monitoring, with steady-state serum targets of greater than 0.5 to 0.7 μg/mL, have been suggested to correlate with improved outcome, although this remains an area of active investigation.[187,302,605] The use of posaconazole as primary therapy for invasive *Aspergillus* infection is also currently being studied.

The polyene amphotericin B deoxycholate (AmBd) and its lipid formulation (LFAB) are active against *Aspergillus* spp., except for *A. terreus*, and exert their activity on the cell membrane. AmBd was the gold standard for serious fungal infections for almost 40 years but now has been supplanted by newer, more effective and less toxic agents. Lipid formulations of amphotericin B can be recommended as alternative therapy for patients unable to tolerate or refractory to voriconazole. The recent consensus suggests that LFAB may be more effective than AmBd in certain settings and is clearly less toxic.[185,708]

Echinocandins have a unique mode of activity; they inhibit the biosynthesis of (1→3)-β-D-glucan in the fungal cell wall, which is absent in mammalian cells, thus offering a high therapeutic index, and additionally have minimal drug interactions.[185,296,431] There are three echinocandins licensed in the United States: caspofungin, micafungin, and anidulafungin. There do not appear to be clinically significant differences among these drugs in spectrum, efficacy, or toxicity. Both caspofungin and micafungin have been investigated for treatment of invasive *Aspergillus* infection, although only caspofungin has been indicated for the treatment of invasive *Aspergillus* infection in patients refractory to or intolerant of other therapies.* Several studies have addressed the safety, efficacy, and dosing of echinocandins in pediatric patients.† All studies have found them to be safe and well tolerated in children, even neonates. Extrapolation of pediatric dosing from adult dosing led to underdosing, which has been revised on the basis of pediatric pharmacokinetic data.[296,297,602,707] Randomized, controlled data on the use of echinocandins for primary treatment of invasive *Aspergillus* infection are lacking.

Combination therapy remains controversial. Possible advantages of combination therapy include synergistic interaction of two drugs with different targets, lower doses leading to less toxicity, greater spectrum of activity, and decreased potential for the development of resistance.[390] Potential disadvantages include antagonistic antifungal activity, increased overall drug interactions, enhanced toxicity, and great increases in cost.[330,475,700] Preclinical data from in vitro and animal studies investigating the use of combinations of antifungal agents against *Aspergillus* are generally promising.[330,475,647,649,700] Complexities and differences in methodologies used to determine in vitro efficacy, experimental design, and animal models confound interpretation of the data and render extrapolating to patients difficult.[475,647,649,723] Clinical data are emerging for patient populations including solid-organ transplant recipients, which demonstrate safety and some promise. Most studies are small, retrospective

†References 217, 262, 296, 453, 501, 646, 707.

studies, often for salvage or intolerance not primary therapy, and with the use of historical controls with LFAB as the comparator to combination therapy, not voriconazole, such that success is hard to define.* Combinations include azoles (voriconazole or posaconazole) with echinocandins or LFAB. Data from prospective, randomized trials in which voriconazole is compared with combinations that include voriconazole are needed to evaluate first-line therapy. Many authors recommend caution in using combination therapy before the results of controlled, prospective investigations are available, even though they acknowledge that widespread use of combination therapy already is evident.† Indeed a survey of invasive *Aspergillus* infection in transplant recipients documented primary combination therapy was used in 35 percent of patients.[44] The most recent IDSA guidelines on the treatment of invasive *Aspergillus* infection conclude that "there are insufficient clinical data to support combination therapy as routine primary treatment…."[708]

No definitive data are available on how long to treat invasive *Aspergillus* infection, although the natural history of disease, assessment of risk factors, and the state and length of immunosuppression, along with investigations on response to therapy and animal studies, inform us on regimens most likely to be effective. Clearly, one must balance the risk for incomplete therapy and recurrent disease with the dangers of increased toxicity and expense from prolonged therapy. One thoughtful approach, based on these many variables, suggests use of the "most effective therapy first for 10 to 12 weeks, or for at least 4 to 6 weeks beyond resolution of all clinical and radiographic abnormalities, whichever is longer."[612] Length of therapy should be individualized, and factors such as recovery from neutropenia or other immunocompromised state, extent of disease, presence of graft-versus-host disease, and coinfections (e.g., with CMV) predict poorer outcome and slower response and probably will prolong duration of therapy for patients with these comorbid findings.

Adjunctive surgical therapy may be recommended for cutaneous and soft tissue infections,[286] for lesions on the great vessels or major airways to prevent massive hemoptysis,[61,99,101,513] in patients with endophthalmitis[717] and osteomyelitis,[344] and for removal of residual lesions before hematopoietic stem cell transplantation is performed. Immunomodulatory strategies to improve host immune response, in theory, are attractive adjuvant therapies. Alveolar macrophages, polymorphonuclear neutrophils, and pulmonary dendritic cells are critical first-line defenses against invasive *Aspergillus* infection.[571] Therefore, modalities that improve the number or function of these cells may improve outcome. Decreasing the use of immunosuppression and corticosteroids as much as possible should be the goal in transplant recipients with invasive *Aspergillus* infection. Additional strategies, including enhancement of T-helper type 1 (Th1) immune responses, exogenous administration of colony-stimulating factors (granulocyte colony-stimulating factor [G-CSF], granulocyte-macrophage colony-stimulating factor [GM-CSF]) or cytokines (IFN-γ) to activate or recruit phagocytes (or both), and G-CSF donor-primed white blood cell transfusions have been investigated and may be used in select cases.* Finally, augmentation of innate pathogen recognition pathways (Toll-like receptors, pentraxins), vaccine strategies, and adoptive immunotherapy have shown promise in animal models of invasive *Aspergillus* and await further refinement and clinical trials.†

When *Aspergillus* causes invasive disease, mortality rates are high (30% to 100%) and notably so for invasive and disseminated or CNS forms of the infection.[98,232,448,637] In a review of English language articles on *Aspergillus* infections in adult lung transplant recipients, the overall mortality rate was 53 percent (59/112); it was 24 percent (9/38) for tracheobronchial or bronchial anastomotic infections, 82 percent (18/22) in patients with invasive pulmonary disease, and 67 percent (2/3) for disseminated invasive infection.[619] These published data reflect the limited therapeutic options previously available (before the advent of extended-spectrum azoles and echinocandins). Several more recent studies suggest improvement in mortality rate (40%) since the widespread use of voriconazole and therapeutic drug monitoring.[43,493,680]

Despite the lack of controlled trials, several surveys document that most lung transplant centers use prophylactic or preemptive systemic antifungal agents (azoles, echinocandins, or amphotericin formulations), aerosolized amphotericin formulations, or both in patients with preoperative or postoperative isolation of airway *Aspergillus*, and almost 60 percent of the centers employed universal prophylaxis.[167,190,191,320,488] Because *Aspergillus* infections are acquired through the lungs and most infections are pulmonary, attaining high pulmonary drug levels via aerosolization and limiting systemic toxicity are attractive options for prevention.[191,627] Multiple trials have suggested a reduction in invasive *Aspergillus* infections with the use of aerosolized amphotericin formulations.‡ A single retrospective study incorporating the use of universal voriconazole prophylaxis with or without inhaled amphotericin compared with targeted itraconazole in lung transplant recipients decreased the rate of invasive *Aspergillus* infection at 1 year from 23.5 to 1.5 percent.[315] Abnormalities in liver enzymes were common, necessitating discontinuation of voriconazole in 14 percent versus 7 percent of the comparator. This study was performed before widespread use of voriconazole therapeutic drug monitoring, the use of which may have precluded some of this toxicity. Based on two phase 2 studies, posaconazole is FDA approved for prophylaxis of invasive fungal infections in certain high-risk patient populations 13 years or older.[139,680] The generalizability of these findings to solid-organ transplant recipients has not been examined. Further randomized, multicenter studies are needed to clarify which agents and prophylactic strategies are most effective.

Prevention of invasive *Aspergillus* infection through environmental controls also is important.[522,534,558,671] Infections with this fungus in transplant recipients can be nosocomial or community acquired. Most germane to prevention is air control, inasmuch as both epidemic invasive *Aspergillus* and sporadic invasive *Aspergillus* correlate with concentrations of *Aspergillus* in the air.[11] A protective hospital environment should consist of high-efficiency particulate air (HEPA) filtration, positive air pressure, high air exchange rate, properly sealed rooms, and removal of carpets, plants, and water-damaged ceiling and floor tiles.[140,195,275,534] Patients should be wearing "fit-tested" masks (N95) when leaving protected environments, efforts should be made to have construction barriers in place, and patient transport routes should be adjusted accordingly if construction is occurring in the hospital and clinics.[522] In addition, monitoring the environment and air for changes in particulates and fungal spores may be considered based on local epidemiology, rates of invasive *Aspergillus*, and infection control practices. When patients are discharged home, they should be counseled to avoid certain high-risk exposure to agents such as excessive dust and molds if possible.[534]

Candida

Although *Candida* infections are the most common cause of fungal infections in solid-organ transplant recipients, the patients at highest risk are abdominal transplant recipients (liver, small bowel and pancreas), with lung transplant recipients at intermediate risk and renal transplants at the least risk.[486,528] The overall rate of *Candida* infections in lung transplant recipients has decreased over time, in one study from 20 percent (1980-1986) to 1.8 percent (2001-2004), as has attributable mortality from 39 to 15 percent.[595] *Candida* infections in lung transplant recipients generally occur early, within the first month after transplantation, associated with long-term broad-spectrum antibiotic therapy, the presence of central venous access and other indwelling foreign bodies, surgical complications, CMV infection, and renal replacement therapy.[362,524,528] Infections present in the form of bloodstream infections are often catheter-associated urinary tract infections, especially if the Foley catheter remains in situ, and respiratory tract infections (tracheitis, pneumonia, and rarely bronchial anastomosis site infections).[528,595,685] Although colonization of the respiratory tract is a common occurrence, primary invasive candidal pneumonia is not. Invasion usually occurs when comorbid conditions are present.[362] In patients with a fungemia workup for metastatic sites, including ophthalmologic examination, echocardiography and imaging may be necessary. Rarely, disseminated disease of abdominal organs and the CNS occurs in solid-organ transplant recipients.[524] The source of infection usually is endogenous, although contributions from donor organs and nosocomial transmission may also occur. Studies have demonstrated changes in species distribution, with a decline in *Candida albicans* infections and increase in non–*C. albicans* species.[524,540] Mirroring these changes, the Transplant Associated Infections Surveillance Network documented an increase in non–*C. albicans* candidal species, which was the driving force increasing azole resistance in *Candida* species (overall 16%), especially for *Candida glabrata* and *Candida krusei*.[405,527] Of interest, the azole resistance of *C. albicans*, *Candida tropicalis*, and *Candida parapsilosis* remained relatively low (1%). In solid-organ transplant recipients, fluconazole resistance was associated with any fluconazole use in the 3 months before infection.

The diagnosis of *Candida* infections can be challenging and requires differentiating colonization from infection because *Candida* spp. are ubiquitous, especially in the upper gastrointestinal and respiratory tracts. In addition, although the diagnosis is often made by culture, these techniques are insensitive especially for invasive disease and, except for blood culture, nonspecific. If recovery of *Candida* spp. from BAL fluid is associated with respiratory symptoms or deterioration of lung function (e.g., increased sputum production), treatment should be considered, although other causes such as rejection and coinfections should be explored as well. Organisms should be identified to the species level because of species-specific susceptibility profiles.[405] Early germ tube determination can confirm the presence of *Candida albicans*, and a negative test can alert the physician to the presence of non–*C. albicans* species, which may have an impact on the choice of antifungal agent.[524] Newer molecular probes, such as peptide nucleic acid fluorescence in situ hybridization (PNA FISH), can identify *C. albicans* rapidly from positive blood cultures.[12]

The Fungitell (1→3)-β-D-glucan assay has been FDA approved as an adjunct for the diagnosis of invasive *Candida*,[528] and its role in the early diagnosis of these infections is still under investigation; it may be especially useful for the diagnosis of deep-seated candidiasis, when blood cultures are known to be insensitive.[492,524] Use of the PCR techniques shows promise, but these techniques are still experimental and their impact on clinical outcome unknown.[42,224,346,492,524] A meta-analysis of PCR on blood samples for invasive candidiasis demonstrated good sensitivity and specificity for candidemia and invasive disease.[42] Whole blood assays using panfungal DNA targets, with subsequent species identification and in vitro sensitivity of at least 10 colony-forming units per milliliter may allow for earlier and more sensitive diagnosis in high-risk patients. The usefulness of these tests in lung transplant recipients with candidal infections is currently unknown. Although galactomannan antigen is also produced by *Candida* spp., this assay is not FDA approved for detection of *Candida* infections.

Although candidemia should always be treated with an antifungal agent, the issue of removal of indwelling catheters has been controversial. The IDSA guidelines for the management of candidiasis and catheter-related bloodstream infections recommend a "qualified yes" regarding the early removal of catheters and suggest that decisions to do so should be individualized, in the presence of the lack of randomized controlled data designed to answer this question.[4,503,527] Two large reviews, performing subgroup analysis from previous controlled trials of patients with invasive candidiasis and candidemia, suggest a nuanced approach as well.[31,80,131,496] Nucci and associates found that the survival benefit demonstrated in univariate analysis was lost in multivariate analysis, which

did not find any clinical benefit to early line removal in 842 adults with candidemia.[496] The accompanying editorial points out that the wide confidence intervals for the odds ratio for survival and the point estimates greater than 1 associated with catheter removal suggest that "clinically meaningful results cannot be excluded … and illustrates a lack of power for evidence against catheter removal."[80] Andes and associates performed a patient-level quantitative review of 1915 adults from seven trials with invasive candidiasis, including 1349 with bloodstream infections. This group did demonstrate a survival benefit from catheter removal.[31] As these authors and the accompanying editorial note, the lack of randomization for catheter removal, standardization of timing of removal and antifungal therapy, lack of data on important high-risk subgroups, and the 15-year time period spanned during the studies are limitations of the data but do lend support to the negative impact of catheter retention.[31,131]

The choice of initial antifungal therapy should be based on azole exposure, dominant species and their susceptibility profiles at the institution caring for the patient, comorbid conditions, sites of involvement, and the use of other medications that might have significant drug-drug interactions.[527] The IDSA guidelines for management of candidiasis recommend fluconazole or an echinocandin in most settings, the latter especially in ill patients with recent azole exposure, with transition to fluconazole when stable.[527] In the study by Andes and associates, treatment of candidemia/invasive candidiasis with an echinocandin was associated with decreased mortality and supports the ascendancy of echinocandins as drugs of choice for most *Candida* infections.[31,131,177] For infections due to *C. glabrata*, an echinocandin is preferred and transition to fluconazole is done only if confirmed results of susceptibility are available. Treatment failures have been noted with the use of echinocandin therapy for *C. parapsilosis*, which has an increased minimal inhibitory concentration to echinocandins, owing to a naturally occurring proline to alanine amino acid change in the *Fks1p* gene, thus leading to a glucan synthase that is 1 to 2 logs less sensitive to echinocandins than *C. albicans*.[228,296] Although this is a common pathogen in neonates, the widespread clinical relevance of this observation is unclear.[31] Fluconazole and AmBd formulations are the drugs of choice, although success with echinocandins is also well documented. Voriconazole or AmBd formulations may be used for selected cases of *C. krusei* or *C. glabrata*, depending on susceptibilities. AmBd formulations with or without flucytosine are still recommended for CNS infections, including meningitis and endophthalmitis, and should be considered for cardiovascular infections (endocarditis, pericarditis, suppurative thrombophlebitis) especially in critically ill patients. Duration of therapy, as with other infections, should be individualized, but treatment should be continued for a minimum of 2 weeks after the last positive culture has been obtained and the signs and symptoms have resolved.[525,527] As noted earlier for *Aspergillus* infections, issues of dosing in pediatrics with the newer antifungal agents and drug-drug interactions should be considered. Several excellent resources are available for detailed treatment algorithms.[524,525,640] Susceptibility testing should be considered on non–*C. albicans* spp. and for *C. albicans* infections that are refractory to conventional therapy. Interpretive breakpoints are available for most common antifungal agents including echinocandins.[15,524,541,542]

Cryptococcus neoformans

Although relatively rare, cryptococcosis is the third most common fungal infection seen in solid-organ transplant recipients, after *Aspergillus* and *Candida*, with an overall incidence of 2.8 percent (0.3% to 5%).[618,663] Available data suggest infection is less common in pediatric patients than in adults.[618,628,696] This infection usually occurs late, after the first year post transplant, but may be earlier in lung transplant recipients.[618,622,663] Disease can be newly acquired but most often in adults is reactivated from latent disease, and cases of donor-derived infection are documented.[243,319,618,663,742] In the latter two scenarios, presentation may be within the first month after transplantation, the occurrence of which is most common in liver transplant recipients.[45,661,663] The overall incidence and time to onset has not changed over many decades, but there are notable shifts in the recent epidemiology. Patients with cryptococcosis are more likely to be lung transplant recipients or multivisceral transplant recipients as opposed to renal recipients. Although CNS involvement and dissemination, with or without fungemia, remains the most common presentation, compared with a prior cohort the presentation of isolated pulmonary infection has become more common in solid-organ transplant recipients. This is especially true since the almost universal use of calcineurin inhibitors.* These immunosuppressants target the fungal homologs of calcineurin, resulting in synergistic interactions with antifungal therapy and increased anticryptococcal activity and thus protecting against disseminated disease.[245,319,353,615,616] Pulmonary infections may have a variety of presentations, including single or multiple nodules, infiltrates, consolidation, and pleural effusion; isolated pulmonary disease may be asymptomatic and detected as an incidental finding. Cutaneous disease manifests as nodular, maculopapular, ulcers or pustules, or cellulitis and most commonly indicates disseminated disease; this finding requires a full evaluation of extent of infection including CNS involvement.[660]

The diagnosis can be made by culture, visualization of encapsulated yeast with India ink or other special stains, and testing for cryptococcal capsular polysaccharide antigen in serum or CSF.[123] Although the serum cryptococcal antigen test is most reliable for CNS and disseminated disease, and a positive test should prompt a full evaluation, it is known to have decreased sensitivity for isolated pulmonary infection; indeed, among solid-organ transplant recipients, lung transplant recipients with isolated pulmonary disease appear most likely to have negative cryptococcal serum antigen.[660,696,699]

The IDSA updated the guidelines for management for cryptococcal disease in 2010.[538] The mainstay of therapy for severe, disseminated disease with CNS involvement

*References 162, 319, 615, 663, 696, 699, 742.

is a combination of an LFAB plus flucytosine, which confers a survival advantage over conventional AmBd—11 percent versus 40 percent mortality in solid-organ transplant recipients.[622,659] Induction therapy should continue for a minimum of 2 weeks and should last 4 to 6 weeks if flucytosine is not used. An extended period of fluconazole maintenance therapy (6 to 12 months) is recommended because relapses are well documented, especially in HIV-infected patients. The risk for relapse in solid-organ transplant recipients and the optimal length of therapy are not known. Duration of treatment less than 6 months has been associated with an increased rate of relapse.[538,614,622] Management of elevated intracranial pressure is essential and may require repeated, sometimes daily lumbar punctures and, rarely, placement of a ventriculoperitoneal shunt.[123,538] For less severe disease localized to the lungs, fluconazole alone may be adequate.[538,622] Mortality rates for solid-organ transplant recipients have improved over time: the overall mortality rate for cryptococcal disease is reported as 11 to 30 percent and varies by site of infection, treatment regimen, type of transplant, and possibly immunosuppressive regimen. The highest rates are seen in liver and kidney transplant recipients with disseminated disease or fungemia, or both (20% to 70%). The lowest mortality rates (3% to 13%) are seen in localized pulmonary disease.*

Immune reconstitution inflammatory syndrome (IRIS) is well described in cryptococcosis in solid-organ transplant recipients and correlates with treatment and the evolving host response to infection, with improvement in cellular immunity as Th1/Th17 responses are resto red.[538,614,623,624,662] IRIS presents in solid-organ transplant recipients a mean of 6 weeks after initiation of therapy and correlates with reduction of immunosuppression. This remains a cornerstone to therapy but should be done in a gradual, stepwise fashion to avoid rapid reconstitution. Manifestations of IRIS include fever, lymphadenopathy, and progression of pulmonary and CNS symptoms and lesions, without documentation of increased titers or positive cultures. Based on observations including the potential benefit of calcineurin inhibitors to antifungal activity and the lack of association of the reduction of corticosteroids on the risk for developing IRIS, consideration should be given initially to tapering corticosteroids, followed by reduction but not discontinuation of calcineurin inhibitors. There is no established therapy for IRIS. Minor manifestations may resolve over time, but IRIS may be life threatening in severe cases and can lead to graft loss.[624] Increasing doses of corticosteroids have been used. Investigational therapies include statins to promote Th2/Tregs over Th1/17 pathways and tumor necrosis factor-α inhibitors.[614,662]

Pneumocystis jiroveci *(Formerly* Pneumocystis carinii*)*

Pneumocystis pneumonia (PCP) is caused by the renamed fungal pathogen *Pneumocystis jiroveci*.[653] PCP has been associated notably with defects in T-cell immunity, as in HIV infection and in patients with leukemia, and with the immunosuppression used in solid-organ transplant recipients. It also is described in patients with other immune defects, including those associated with corticosteroid use and radiation therapy, neutropenia, and congenital immunodeficiency.[436,567] Serologic data suggest universal, albeit asymptomatic, infection occurs by 4 years of age. In most cases, symptomatic PCP in an immunocompromised host is thought to be reactivation of latent infection, although putative nosocomial person-to-person transmission linked by molecular evidence is increasingly observed.[153,163,384,549,598]

Heart-lung recipients and lung transplant recipients are at increased risk for developing infection, with reported attack rates of 6.5 to 43 percent without prophylaxis, up to a 10-fold increase as seen in heart transplants alone.[568] Higher rates of infection in solid-organ transplant recipients, including lung transplant recipients, have been associated with CMV coinfection, use of cyclosporine and corticosteroids, and receipt of therapy for rejection; cases can occur many years after transplantation.[474,549,598,715] Therefore, guidelines recommend a benefit of long-term and perhaps lifelong prophylaxis, especially if additional risk factors are ongoing.[568,598,715] The drug of choice for prophylaxis remains TMP-SMX, and its use is associated with dramatic decreases in the incidence of PCP infection. Additional benefits of this drug include prevention of many community-acquired respiratory, gastrointestinal, and urinary tract pathogens and protection against most *Toxoplasma gondii* and *Nocardia* infections. Multiple regimens exist, and dosing for 3 days per week appears to be as effective as is daily dosing in all populations studied. Toxicity remains an issue for some patients and includes bone marrow suppression, decreased renal function, hepatitis, and rash (Stevens-Johnson syndrome), which may be severe. Alternative regimens exist for patients intolerant of TMP-SMX, but they should be considered second line because of breakthrough PCP infection or diminished coverage of non-PCP pathogens. Such alternatives include pentamidine, dapsone, atovaquone, and clindamycin/pyrimethamine. Details of these regimens are reviewed elsewhere.[567,598]

PCP infection is manifested as progressive dyspnea, cough, tachypnea, chest pain, and cyanosis over the course of days to weeks. In addition, fevers, sweats, and flulike symptoms may be prominent. Hypoxia and shortness of breath, in the context of normal or minimal findings on chest radiographs, are common findings. Corticosteroids and calcineurin inhibitors may alter the signs and symptoms and render early diagnosis more difficult to establish. The diagnosis is confirmed by identification of *P. jiroveci* in a respiratory sample or lung tissue. Immunofluorescent staining of organisms with monoclonal antibodies had been the technique of choice; Gomori methenamine silver nitrate, which stains cyst forms only (5% to 10% of the total organisms), is the most reliable staining method.[567] BAL fluid and tissue obtained by open-lung biopsy have the highest diagnostic yield.[567] Recently, PCR assays on BAL specimens have been recognized as highly sensitive and specific diagnostic techniques and are now commercially available. This assay may allow the distinction between colonization and low

*References 162, 614, 615, 622, 659, 696, 742.

fungal burden infection.* (1→3)-β-D-Glucan is a component of the *P. jiroveci* cell wall and can be detected in the serum of patients with PCP.[143,171,355,594] This assay appears to be a reliable marker of infection, with the most convincing results shown in patients with HIV infection.[171] At this time, it cannot be recommended to supplant appropriate testing of respiratory samples, but it may be considered as an adjunct for diagnosis, especially in patients too ill to undergo invasive procedures.[473]

The mainstay of therapy for severe PCP infection remains high-dose TMP-SMX for 14 to 21 days.[209,436] Therapy can be continued through mild adverse events, such as rash and minimal perturbations in aminotransferase levels and complete blood cell counts. Dose reduction, desensitization, or both may be helpful, and renal dosing should be implemented for renal dysfunction. Corticosteroids are generally recommended for severe disease, including a 5- to 7-day course with a slow taper over 7 to 14 days. For patients intolerant of TMP-SMX or those less seriously ill, alternative therapies can be considered, including dapsone with trimethoprim, atovaquone, intravenous pentamidine, trimetrexate, clindamycin/primaquine, and pyrimethamine/sulfadiazine.[209,436] Relapse in patients without HIV infection is an uncommon occurrence with TMP-SMX therapy if a reduction in immunosuppression can be accomplished and coinfections such as with CMV do not occur.

Endemic Mycoses

Endemic mycoses, or the dimorphic fungal infections histoplasmosis, blastomycosis, and coccidioidomycosis, are rare but important causes of disease in solid-organ transplant recipients.[555] Spores are inhaled from the environment and convert to noncontagious yeast forms at 37° C. Infection may be caused by latent reactivated disease in the recipient or donor or may be newly acquired. Because of the nonspecific findings, latency of these organisms, increased worldwide travel, and organ procurement strategies, infections in transplant recipients require a high index of suspicion, especially if they occur in nonendemic areas.

Coccidioidomycosis, caused by *Coccidioides immitis* and *Coccidioides posadasii*, is the endemic mycosis most commonly seen after transplantation. It occurs in up to 9 percent of solid-organ transplant recipients in endemic areas of the southwestern United States (especially California and Arizona), northern Mexico, and Central America.[68,69,692] Unlike histoplasmosis and blastomycosis, pretransplant infection poses an increased risk for development of serious posttransplant disease. Transplant candidates should be screened for a history of coccidioidomycosis and environmental exposure, which should prompt serologic testing for *Coccidioides*. Secondary prophylaxis is very effective and should be given to all patients with a history of *Coccidioides* infection; without its use, the mortality rate is very high (up to 70%).[68,339,555,692] Pulmonary infections may be accompanied by an acute onset of respiratory symptoms and fever and progress rapidly to respiratory failure. Nonspecific symptoms of anorexia, weight loss, and fatigue may herald extrapulmonary disease. Dissemination to bones, skin, and the CNS occurs commonly when infection occurs in transplant recipients. The time of highest risk appears to be in the first 3 months after transplantation, with the majority of infections occurring by 1 year. Donor-derived coccidioidomycosis has been documented in lung transplant recipients.[70,458,555,676,740] Recipients did not have evidence of pretransplant coccidioidomycosis, nor did they live or travel to endemic areas. Several of the donors had documented epidemiologic risk factors. Commonly these lung transplant recipients had fulminant pulmonary or disseminated infections within the first 3 weeks after transplantation, the majority of which were fatal.

The diagnosis of coccidioidomycosis can be made definitively by culture, usually from respiratory samples or urine and rarely from blood or CSF.[32] Histopathologic evaluation may reveal large spherules with the presence of endospores. Serologic tests include tube-precipitin antigen (IgM), detected early in disease, and complementation fixation or immunodiffusion (IgG), which can be titered and is helpful in monitoring response to therapy.[32,68] Immunocompromised patients may have negative serologic studies. Skin testing for delayed hypersensitivity no longer is available in the United States. The optimal therapy for solid-organ transplant recipients with coccidioidomycosis is unknown but generally follows published guidelines.[226,555] For mild pulmonary disease, fluconazole or itraconazole is appropriate in most cases. Most experts suggest that patients with rapidly progressive, nonmeningeal disease should receive LFAB until their condition is stabilized, followed by a prolonged course of azole therapy (fluconazole, itraconazole, possibly voriconazole or posaconazole). For meningitis, high-dose azoles are indicated, probably lifelong. Patients with evidence of previous infection should receive secondary prophylaxis with azole therapy for a minimum of 6 to 12 months after undergoing transplantation.[32,68,226,555] Echinocandins should not be used for endemic fungal infections.

Histoplasma capsulatum infection is a rare occurrence after transplantation, even in patients with presumed pretransplant infection. Cases in transplant recipients have been observed in endemic areas and in conjunction with outbreaks in areas hyperendemic for histoplasmosis, the Mississippi and Ohio River valleys, and Central America.[148,259,681] Two cases of histoplasmosis in renal transplant recipients were linked by molecular typing to donor-derived disease.[393] A 10-year experience of 3436 solid-organ transplant recipients in Ohio observed 14 cases of posttransplant infection, all with dissemination, but with good response to prolonged therapy.[148] Median time to diagnosis was 17 months after transplant, and time from onset of symptoms to diagnosis was 3 weeks, reflecting the protean nature of initial presentation. Fourteen additional patients had evidence of histoplasmosis in explant or donor tissues; all received antifungal prophylaxis and none developed active infection.[725] Manifestations of infection include pulmonary, mediastinal, inflammatory, and disseminated syndromes with or without CNS involvement. The diagnosis can be made

*References 10, 74, 193, 279, 395, 509, 590.

by culture, histopathology, serology, or antigen detection.[725] In immunosuppressed patients with disseminated disease, culture of appropriately obtained specimen, and antigen detection (urine, serum, BAL) appear to be the most useful (sensitivity of 80% to 100% using third-generation assays).[259,271,274,721] Cross reactivity with *Aspergillus* and *Blastocystis* can result in false-positive *Histoplasma* antigen tests with these infections.[689] In addition, positive galactomannan antigen assays have been reported in solid-organ transplant recipients with histoplasmosis.[689] Guidelines recommend long-term therapy (3 to 4 months) with LFAB for immunocompromised patients with disseminated or CNS involvement, followed by 6 to 12 months of itraconazole.[555,726] Voriconazole and posaconazole have good in vitro activity and have been successfully used as well.[219,220] Monitoring antigen levels is beneficial to assess response to therapy and for relapse.[272,721,726]

Blastomycosis dermatitidis, the causative agent of blastomycosis, appears to be the least common endemic fungal infection in the posttransplant setting.[231] These infections are rare events in series of fungal infections in immunocompromised patients, including patients with the acquired immunodeficiency syndrome, even in endemic areas of the south central and north central United States, particularly in the Ohio and Mississippi River valleys and around the Great Lakes.[555] Cases of posttransplant disease most commonly present as pulmonary disease, which may lead to acute respiratory distress syndrome and a high mortality rate. Diseases of the skin and CNS are also common.[259,336,603,689] Diagnosis is made by histopathology, culture, and antigen detection.[121,138,555] Guidelines for therapy recommend immunocompromised patients should receive LFAB until stabilized (4 to 6 weeks), followed by a prolonged course (6 to 12 months) of an azole.[120,121,555] Most data are available for itraconazole, although voriconazole and posaconazole also may be effective.[121,336]

*Emerging Non-*Aspergillus *Mycelial Fungi*

The impact of non-*Aspergillus* mycelial fungi is currently unknown for lung transplant recipients. Published reports suggest that these mold infections are becoming increasingly common and are recognized pathogens in lung transplant recipients and other solid-organ transplant recipients.* These organisms include non-*Aspergillus* hyalohyphomycetes or hyaline hyphae without pigment (*Scedosporium apiospermum*, *Fusarium* spp.); phaeohyphomycetes, or dematiaceous pigmented molds (*Cladophialophora bantiana*, *Scedosporium prolificans*, *Exophiala jeanselmei*, *Pyrenochaeta romeroi*, *Cladosporium* spp.); and Zygomycetes, or nonseptated hyphae (*Rhizopus* spp., *Mucor* spp.).[363] Many of these organisms have unique susceptibility profiles, which include the newer azoles, voriconazole and posaconazole, as well as LFAB and terbinafine. Frequent poor outcome has prompted the use of combination therapy, although without conclusive data.[185,363,641] Indeed, these infections may be more likely to be disseminated and fatal than those caused by *Aspergillus* spp.[310] Surgical débridement may play an important role in therapy in addition to medical therapy.[363]

Viral Infections

Cytomegalovirus (CMV)

The epidemiology of CMV infection in solid-organ transplant recipients has changed in recent years. Advances in diagnosis and in preemptive and prophylactic strategies and therapy have decreased the impact of early CMV infection in transplant populations. However, once antiviral therapy is discontinued, CMV infection is common in high-risk patients and it remains one of the most important pathogens in solid-organ transplant recipients, with wide-ranging effects on morbidity and mortality.[160,307,308,463] Thus, continued efforts to optimize preventative strategies are paramount.[463,520,533] The source of infection can be endogenous reactivation or from the donor graft or leukocyte-containing blood products and cause primary infection or reinfection. Rarely, primary infection may be acquired from the community, especially in young children.

The effects of CMV infection have both profound direct and indirect consequences. As per published definitions, direct effects of the virus range from "asymptomatic" CMV infection, which can be detected by viremia (culture positive), antigenemia (pp65 in leukocytes), and DNAemia or RNAemia (generally by quantitative PCR methods); CMV syndrome with viremia, fever, neutropenia, thrombocytopenia; to true end-organ disease, which is often found primarily in the allograft but may disseminate. The diagnosis of end-organ disease, such as pneumonitis, enteritis/colitis, hepatitis, and encephalitis/meningitis, requires signs or symptoms of disease at that site, with detection of CMV by culture, histopathology, immunohistochemical staining, or in situ hybridization. Except for CNS disease, detection by PCR is not sufficient for establishing the diagnosis because it is probably too sensitive and may signify transient viral shedding. In addition, the identification of co-pathogens is important and may confound the diagnosis.*

The indirect, immunomodulatory effects of CMV have broad-reaching consequences and can be divided into three categories: (1) immunomodulation as it contributes to the net state of immunosuppression and increased risk for opportunistic superinfections (e.g., aspergillosis, PCP); (2) increased risk for oncogenesis, such as seen with EBV-related lymphoproliferative diseases; and (3) allograft injury and dysfunction, as seen in classic rejection and vasculopathy of the allograft. In lung transplant recipients, bronchiolitis obliterans syndrome, a severe form of chronic rejection (small airways disease), has been associated with CMV infection.[403,579,746] Of interest, in a retrospective, multicenter study of almost 600 pediatric lung transplant recipients, development of bronchiolitis obliterans syndrome in the first year (14%) was not associated with CMV infection.[160]

The greatest risk factor for developing CMV infection in children, as in adults, is donor/recipient (D/R)

*References 160, 309, 358, 403, 573,745,746.

seropositivity, most notably D+/R– mismatch, followed by D–/R+ mismatch. Infection can occur in D+/R+ and rarely in D–/R– matches.[155,160] Other risks include the use of induction therapy, antilymphocyte antibody, and blood product transfusion (performed previously).[746,747] In pediatric lung transplant recipients, the risk for CMV infection has also been associated with living donor transplant, older age at transplant, and multiple episodes of A2 rejection before CMV.[160] The incidence of CMV infection in lung transplant recipients is higher than that in other solid-organ transplant recipients. The reasons are multifactorial but include long-term, intense immunosuppression and high levels of CMV latency, viral load, and reactivation associated with the lung and its transplantation.[50,747] The incidence of infection and disease is reported to be 54 to 92 percent without prophylaxis.[746,747] The rates of CMV infection, and its consequences, have been considerably decreased by utilizing various preventative strategies (see later discussion), although different study design, end points, and follow-up periods point to the difficulty in identifying the optimal regimen and time course.[160,520,533,746]

A combination of approaches are employed to reduce the incidence of CMV infection. The use of CMV-negative or leukocyte-free blood products for CMV-negative recipients is standard practice in most transplant centers and has been shown to reduce infection rates. Matching of D/R serologic status probably would reduce infection rates but also would limit the donor pool for recipient-negative recipients significantly and is not considered to be indicated. The final strategies use different regimens of antivirals to suppress replication with or without immunoglobulin products for enhanced passive immunity.[579,746] These regimens can be prophylactic, in which all patients at risk are treated for a certain period, or preemptive, in which highly sensitive screening techniques, such as antigenemia (pp65) or DNAemia, are used to identify patients needing therapy. The rationale of this approach is to limit drug exposure, thereby decreasing toxicity and viral resistance. To complicate matters, regimens can include multiple antiviral agents, such as intravenous ganciclovir or acyclovir and/or oral ganciclovir, acyclovir, or valganciclovir for various periods. Several surveys of lung transplant centers (adult and pediatric) show a preponderance of the use of universal prophylaxis, based on serostatus stratification.[156,749] Centers used a variety of antiviral agents, although intravenous ganciclovir and/or valganciclovir were most commonly used, and the duration of therapy ranged from 3.5 weeks to indefinitely, but most used 12 weeks. In addition, many responding centers used CMV intravenous immunoglobulin (IVIG) with variable schedules, although the benefits of its use need further study.[72,557,745,748] Methods and regimens for viral monitoring also varied greatly. These surveys highlight the need for additional data, some of which is now available, including a randomized controlled trial comparing 3 versus 12 months of valganciclovir in adult lung transplant recipients.[465] This study and others provide evidence that for high-risk lung transplant recipients, universal prophylaxis and extending prophylaxis beyond 3 months to 12 months and possibly "indefinitely" has an overall beneficial effect in terms of CMV infection and its consequences.* In adult lung transplant recipients receiving valganciclovir prophylaxis, drug-resistant CMV infections, including some that resulted in death of the patient, were documented, although drug-resistant strains were not observed at higher rates than previously documented for lung transplant recipients.[635]

Although increasing the length of prophylactic antiviral therapy may decrease the incidence of CMV infection, additional complexity relates to the resultant immature T-cell response associated with long-term and potent antiviral suppression, whereas some "escape" may allow a protective T-cell response after therapy is discontinued.[579] In addition, the concern remains for the creation of drug-resistant CMV infection in the presence of long-term antiviral exposure. Rates of resistant CMV remain relatively low, in spite of broad use of antiviral agents for prophylaxis, although they are highest in lung transplant recipients among the solid-organ transplant recipients; this is believed to be secondary to intense immunosuppression and high viral load associated with lung tissue.[520,732] A study in high-risk adult renal transplant recipients documents a higher incidence of drug-resistant isolates in preemptive strategies, designed to decrease drug exposure.[145] This supposed contradiction may be explained because the higher viral loads were seen in these patients, because by definition they were viremic before antiviral agents were initiated and because of the use of oral valganciclovir, rather than intravenous therapy, during periods of high replication; both are risk factors for resistance.[210]

Several evidence-based consensus guidelines by expert advisory groups on the management of CMV infection in solid-organ transplant recipients have been published and are summarized here[309,358,747]:

1. All D+ or R+ lung transplant recipients should be considered for prophylaxis.

2a. Prophylaxis should continue for a minimum of 180 days, although some pediatric experts would limit this to 3 months, given the risk for catheter-associated infection if intravenous ganciclovir is used.

2b. The drug of choice for prophylaxis is intravenous ganciclovir or oral valganciclovir.

2c. Combination prophylaxis with CMV IVIG may be considered, if available, because some evidence suggests that its use may reduce infection rates further.

3a. Monitoring should be performed every 2 weeks for the first 6 months after transplantation to assess for breakthrough viremia and disease and then periodically for 8 to 12 weeks after completion of prophylaxis.

3b. Whole-blood quantitative PCR assay is the monitoring method of choice and should be validated at each center.

3c. If a preemptive approach is being used, CMV monitoring should be performed more frequently.

4. Breakthrough disease should be treated with ganciclovir 5 mg/kg administered intravenously every

*References 160, 236, 307, 463, 520, 533, 732, 748.

12 hours for up to 21 days, until the viral load is below detection. Immunosuppression should be reduced if possible.

5. Infection that occurs after the initial prophylaxis has been stopped should be treated with ganciclovir or valganciclovir until the viral load is below detection.

6a. Resistance should be considered in patients with breakthrough viremia, recurrent infections, or poor response to therapy. Genotypic analysis for common mutations (UL97 [viral kinase] and UL54 [DNA polymerase]) should be performed on isolates recovered from these patients.

6b. Foscarnet is the drug of choice, with or without ganciclovir, for possible resistant strains.

7. Reinitiation of prophylaxis should be considered in patients requiring antilymphocyte antibodies or high doses of corticosteroids for rejection.

Of note, valganciclovir is not FDA approved for prophylaxis in lung transplant recipients, although it is for other solid-organ transplant recipients, and available data suggest that it is safe and effective in lung transplant recipients as well.[307,463,520,732,747] Data in pediatric patients for the safety and efficacy of valganciclovir for prophylaxis and treatment are emerging. Some preliminary data on formulations and pharmacokinetics are available and support concerns for underdosing, leading to resistance and some hematologic toxicity.[103,435]

Epstein-Barr Virus/Posttransplant Lymphoproliferative Disorder

The disease manifestations of primary EBV infection in solid-organ transplant recipients range from uncomplicated mononucleosis (fever, malaise, exudative pharyngitis, lymphadenopathy, hepatosplenomegaly, atypical lymphocytosis) to conditions indistinguishable from malignant lymphoma. Organ-specific disease may include pneumonitis, hepatitis, as well as gastrointestinal, CNS, and hematologic involvement. Early lesions of EBV-driven lymphoproliferation, such as plasmacytic hyperplasia, are seen in mononucleosis-like syndromes, within the context of normal tissue architecture. The term *posttransplant lymphoproliferative disease* (PTLD) is generally reserved for proliferation of EBV-positive immunoblasts and atypical lymphocytes associated with effacement or destruction of normal tissue architecture. These disorders can be classified further into polymorphic or monomorphic PTLD and finally malignant lymphomas that may contain clonal chromosomal abnormalities. These tumors are characterized by rapid and progressive growth despite a reduction in immunosuppression. Fatal non-PTLD viral syndromes can occur in solid-organ transplant recipients as well. The reader is referred to several excellent, in-depth reviews and guidelines.[18,253,552,553,666]

The manifestation of EBV/PTLD is varied and depends on the site of involvement, which may be intrathoracic, extrathoracic (abdominal, head and neck, CNS), or disseminated and intranodal or extranodal.[392] Often, PTLD is seen in the allograft, as with lung, liver, and intestinal transplantation.[253] Signs and symptoms of PTLD can be nonspecific, such as fever of unknown origin, malaise, weight loss, and sore throat.[76] Abdominal pain, gastrointestinal bleeding, intestinal obstruction and perforation, allograft dysfunction such as changes in respiratory status in lung transplant recipients, diffuse lymphadenopathy on physical examination or CT, or hepatosplenomegaly should raise the index of suspicion for PTLD. Focal neurologic findings also can be seen with CNS disease. An additional challenge is to differentiate allograft rejection from PTLD; both entities in lung transplant recipients may be characterized by allograft dysfunction with diffuse consolidation on imaging, without obvious lymphadenopathy or a mass. Because the therapies for these two conditions are diametrically opposed, increasing or decreasing immunosuppression, this distinction obviously is critical.[253,553]

Risk factors for the development of PTLD have been identified.[18,76,134] Pretransplant EBV seronegativity (as a surrogate marker for the risk for development of posttransplant primary EBV infection) is probably the most important predisposing factor for the development of PTLD. Because primary EBV infection occurs almost universally by the time of adulthood, older individuals are already immune and young children undergoing transplantation are therefore at greatest risk. Presumably, it is the lytic phase of the primary EBV infection that sets the stage for PTLD, because the delayed EBV-specific cytotoxic T lymphocyte (CTL) response observed in immunocompromised children allows for high viral loads and uncontrolled B-cell infection, latency, and reactivation.[18] In addition, concomitant CMV infection or CMV mismatch before transplantation increases the risk for developing PTLD, contributing to the "net state of immunosuppression." Certain immunosuppressive regimens, such as the use of OKT3 and polyclonal antilymphocyte antibodies and possibly tacrolimus in pediatric patients, are linked to the development of PTLD, although it is likely that the overall intensity of immunosuppression, not a specific agent, is most important in defining the risk for development of PTLD.

Patients at highest risk by type of transplant are small bowel recipients, followed by recipients of hearts and lungs and livers. This risk is probably multifactorial and includes more intense immunosuppressive regimens and transplantation of large amounts of lymphoid tissue with the graft, thereby increasing recipients' potential exposure to donor-derived EBV. The published incidence of PTLD in pediatric lung transplant recipients ranges from 7.7 to 26.3 percent.[76,134,545] PTLD most often occurs within 12 months after transplantation, with median onset of primary infection at 6 weeks and symptoms presenting in the 2- to 3-month range.[18,76] When late PTLD occurs, it is associated with older recipients, long duration of immunosuppression, EBV-negative disease, and poorer prognosis.[134,199,379]

The diagnosis of PTLD requires a high index of suspicion. The gold standard is histopathologic examination of tissue. Specimens should be processed by pathologists familiar with the morphologic classifications (e.g., phenotype, lineage, clonality) and ancillary tests that may be helpful, such as tissue staining for EBV-encoded RNA

2 by in situ hybridization (EBERS), which is more sensitive than in situ targeting viral DNA or the use of immunohistochemical staining of latent antigens (EBNA-1 and 2, LMP-1) and more specific than EBV DNA amplification; the expression of CD20, which has implications for therapy, should also be determined.[18,552] Imaging also can be used for presumptive diagnosis, to guide biopsy, and for follow-up.[545,607] In lung transplant recipients, CT of the chest may reveal discrete nodules, air space consolidation, or mediastinal lymphadenopathy. Extrathoracic involvement is less common but may include abdominal lymphadenopathy, liver and spleen lesions, and a thickened bowel wall. Head and neck imaging may reveal involvement of cervical lymph nodes, pharynx, orbit, sinus, and rarely the brain. Fluorodeoxyglucose-labeled positron emission tomography combined with CT (FDG-PET/CT) in adult and pediatric solid-organ transplant recipients with PTLD may offer a more nuanced approach to diagnosis and staging and may be particularly helpful in management to distinguish between active versus necrotic/fibrotic lesions.[62,66,415]

Viral load determination (quantitative PCR) from blood should be sought in patients with a concern for PTLD. Although an elevated load may support the diagnosis, the value of a single measurement is uncertain; no diagnostic threshold level has been identified. In addition, these assays are not standardized, and many questions remain regarding their use, including which compartment is most revealing and should be sampled (peripheral blood lymphocytes, whole blood, or serum), extraction methods, thresholds for initiation of therapy, and the effect of serostatus on the sensitivity and specificity of viral loads.* Because of significant interlaboratory variability, longitudinal testing of patient samples should be performed at a single site. Finally, not all patients with EBV/PTLD have elevated viral loads and viral loads may be elevated without evidence of disease; therefore, PCR assays lack sensitivity and specificity for PTLD.[18,65] Although these assays are now widely used at transplant centers, further controlled studies are necessary to optimize their use in immunocompromised patients.

Patients at the highest risk for PTLD and mortality are those in whom primary EBV infection develops early after transplantation; therefore, every effort should be made to identify these patients. Pretransplant serologic assessment of donors and recipients for both EBV and CMV can alert physicians to most of these high-risk patients, because donor/recipient mismatch of either virus appears to play an important role in risk stratification.[76,134] Once identified, these patients should be monitored by PCR assay for evidence of primary infection, and careful examination and use of CT for early diagnosis of disease should be included. Several strategies have been used for the prevention of EBV/PTLD in high-risk patients.[253,553] The use of EBV-negative donors, although probably effective, would reduce the donor pool substantially and generally is not advocated. The use of prophylactic antiviral therapy has not been proved to prevent the development of PTLD. Although these agents are active against the lytic viral infection that precedes PTLD, they are not active against the latent viral phase that characterizes PTLD. Theoretically, antiviral agents may decrease the number of newly infected cells, thus impacting viral loads. Acyclovir and ganciclovir are often used for prevention of CMV, and comparisons of the incidence of PTLD in certain high-risk patients receiving these antiviral agents suggest some benefit; however, PTLD has developed in some patients while receiving these agents.[161,223] A small prospective controlled study of high-risk (D+/R–) pediatric renal transplant recipients found valganciclovir prophylaxis to significantly reduce the incidence of primary EBV infection, lower viral loads in those who became infected, and less symptomatic disease associated with infection but did not investigate the link to PTLD.[292] The use of IVIG or CMV IVIG is similarly a potential, but unproven strategy.[251,253,306] Given insufficient evidence, universal and routine use of antiviral agents and IVIG products for prophylaxis and preemption has not been endorsed by the American Transplant Society.[18]

Preemptive strategies aimed at identifying primary infection by blood PCR monitoring have received significant attention.* In these protocols, high-risk patients undergo EBV quantitative viral load monitoring at frequent intervals (usually weekly) to identify increases associated with infection, which is a prerequisite for the development of EBV/PTLD. Patients with a persistently high viral load should be evaluated aggressively for the presence of PTLD on examination and imaging, and suspicious lesions should be sampled. When the diagnosis of PTLD is made, immunosuppression should be decreased as much as feasible, the optimal duration of which is uncertain.[18,383] Most patients with nonmalignant lesions will respond to this maneuver alone. Return to higher levels of immunosuppression is usually prompted by rejection or clear evidence of clinical and virologic response. The use of antiviral agents in this setting has become routine, although without proven benefit.[18] Surgical resection and local radiation therapy may be beneficial for localized disease and in the event of gastrointestinal involvement. Characterization and outcome of patients with chronic high viral loads, without evidence of PTLD, is emerging. These studies suggest that up to 45 percent of patients will progress to PTLD up to 8 years after transplant.[65] Efforts to immunologically define and identify this high-risk group are ongoing.[410,411] Risk factors for poor outcomes include poor performance status, multisite disease, CNS involvement, T or NK cell– and EBV-negative PTLD, monoclonal disease, and presence of certain oncogenes or tumor suppressor genes.[18]

Monoclonal B-cell antibody therapy has become an attractive option for $CD20^+$ lesions not responsive to a reduction in immunosuppression.[18,553] The currently available product is an anti-CD20 antibody (rituximab). Reports document initial response rates of 40 to 60 percent, although relapses are not uncommon.† A

PTLD-specific prognostic index identified high-risk patients with a 0 percent 2-year survival, in contrast to 50 percent in intermediate and 88 percent in low-risk adult patients receiving rituximab for PTLD; this highlights the potential heterogeneity of the patients and outcomes.[129] These high-risk patients all required additional chemotherapy, and 55 percent died of PTLD. Although generally well tolerated, long-term hypogammaglobulinemia is a common occurrence in recipients, and viral complications, such as severe CMV and hepatitis B and C infections, as well as parvovirus B19–induced aplasia and enteroviral meningoencephalitis, have been associated with its use.[553] For refractory disease, cytotoxic chemotherapy may be indicated, in consultation with oncology colleagues. The preliminary data on the use of adoptive immunotherapy (autologous and allogeneic EBV-specific cytotoxic T lymphocytes) show promising expansion, persistence, and efficacy of cytotoxic lymphocytes.[277,593] The generation of calcineurin-resistant T-cell clones is expected to improve the performance of cytotoxic lymphocyte therapy in the presence of ongoing immunosuppression.[84] Other investigational therapies include immunomodulatory therapy (anti–interleukin-6, Th1 response with IFN-α), interruption of viral signaling pathways (LMP1, LMP2a), and vaccine technology.[18,249,278,553]

Other Herpesviruses: Herpes Simplex Viruses Types 1 and 2, Varicella-Zoster Virus, Human Herpesviruses Types 6, 7, and 8

Infections with herpes simplex virus (HSV) types 1 and 2 are common occurrences in solid-organ transplant recipients; and in older children and adults, HSV usually is a reactivation disease manifested as orolabial or genital disease. Primary disease occurs in young children who contract the infection from viral shedding of close contacts. Serostatus of transplant candidates should be determined because symptomatic reactivation occurs in up to 68 percent of seropositive solid-organ transplant recipients not receiving prophylaxis and naïve recipients are at risk for severe and prolonged primary infections.[750] In lung transplant recipients, serious or disseminated disease such as esophagitis, hepatitis, and pneumonitis can occur.[633] Infections tend to occur early, within the first month after transplantation, unless prophylaxis is used. As with other herpesviruses, concomitant infection with CMV is not an uncommon event. The diagnosis can be made clinically when typical lesions are present. Culture and PCR technology can confirm the diagnosis and be helpful for unusual manifestations. PCR has advantages of rapidity, increased sensitivity, and identifying HSV in blood and other body fluids. Prophylactic strategies with acyclovir or ganciclovir used for CMV (3 to 6 months) can prevent HSV. Generally, prophylaxis for HSV infection does not need to be continued past the early transplant period unless there are frequent clinical recurrences, in which case suppressive antiviral therapy should be continued until reduction of immunosuppression can occur. Occasionally, lifelong suppression may be necessary. Intravenous acyclovir and oral valacyclovir or famciclovir are effective therapies for localized mucocutaneous disease. More severe disease should be treated with intravenous formulations until resolution of symptoms. Resistance of HSV in solid-organ transplant recipients is rare, but when it is suspected in instances of clinical failure, culture and susceptibility should be performed. Most resistance results from changes in the viral thymidine kinase gene, which is necessary to initiate the triphosphorylization for active antiviral activity (inhibition of DNA chain elongation).[548] Foscarnet, which does not require phosphorylization, is usually the drug of choice. Less frequent mutations with altered DNA polymerase may require cidofovir. A new lipid ester of cidofovir, CMX001, which has broad and potent antiviral activity and less toxicity, is currently in phase 3 trials for treatment of several DNA virus infections.[554]

Primary varicella-zoster virus (VZV) infection can occur in pediatric lung transplant recipients, as can reactivation of previous disease leading to herpes zoster. The rates of VZV infections in solid-organ transplant recipients are not known, but presumably the infection rate after transplantation is low, since the widespread use of varicella vaccine (Varivax), as it is in the general community.[27] Because VZV infection is a vaccine-preventable disease and complications of primary infection can be life threatening, all patients should be screened for evidence of immunity, and seronegative transplant candidates should receive varicella vaccine.[4,157,539] Available data demonstrate that this vaccine is safe and effective in this setting, although seroconversion rates may be reduced. Optimally, two doses 4 to 6 weeks apart and a minimum of 2 to 4 weeks before transplant should be administered. If the vaccine does not prevent disease, it should mitigate development of severe disease. In addition, susceptible family members also should receive the vaccine. The zoster vaccine (Zostavax) has a 14-fold higher virus titer and theoretically could pose a higher risk for complications in immunocompromised patients.[130,157] It is indicated for patients older than 60 years of age with a history of VZV infection. It may be considered in adult transplant candidates with serologic evidence of VZV at least 2 months before transplant; there is no indication for pediatric patients. Exposure in posttransplant patients should be treated with a high-titer varicella immunoglobulin preparation if available (VZIG is no longer manufactured; VariZIG remains unlicensed and available through IND application only); IVIG is recommended based on the "best judgment of experts" if high titer preparations are not available, although no clinical data document its efficacy. The window for benefit of administration of immunoglobulin preparations has been extended from 4 to 10 days after exposure.[27,111] Additionally, some experts recommend the use of prophylactic acyclovir if exposure such as household or intimate contact is likely to lead to development of disease or is revealed past the window for immunoglobulin prophylaxis to be effective. Varicella vaccine, which is an attenuated live viral product, generally is not recommended in posttransplant recipients at this time. Limited data suggest that it is safe and may ameliorate disease in some immunocompromised patient populations, such as those with leukemia, HIV infection, or renal transplants.[94] VZV infection in lung transplant recipients should be

treated with intravenous acyclovir until all lesions are crusted and the patient's symptoms have lessened.[539] Patients taking corticosteroids, especially during the incubation period, are at increased risk for the development of severe disease. Hemorrhagic and disseminated disease, including encephalitis, hepatitis, and pneumonitis, can occur in immunocompromised patients. All patients admitted to the hospital with VZV infections should be placed in combined airborne precautions; immunocompromised patients may shed virus for a prolonged period. Hospitalized lung transplant recipients who have received immunoglobulin postexposure prophylaxis should remain in isolation from day 10 to day 28.[539]

Herpes zoster is a common event in adult transplant recipients; rates in children have not been published for solid-organ transplant recipients. A study of solid-organ transplant recipients aged 16 to 74 years found a 15 percent incidence of herpes zoster in lung transplant recipients, with a mean time to onset of 14 months and a median of 9 months (9 days to 5.8 years).[247] The diagnosis is made clinically and with the use of viral culture or PCR techniques if necessary. Infections can become disseminated, as evidenced by multiple dermatomal spread, and should be treated with intravenous acyclovir and pain control. The use of corticosteroids should be decreased, if possible.

HHV-6, variants A and B, the latter of which is most commonly implicated in human disease, is an emerging opportunistic viral pathogen. Seropositivity reaches nearly 100 percent in early childhood, and HHV-6 is responsible for febrile illnesses with or without gastrointestinal or upper respiratory tract symptoms, febrile seizures, roseola (exanthema subitum, sixth disease), and asymptomatic infection in normal infants and young children.[19] Therefore, disease in all but the very youngest transplant recipients probably represents reactivation. Several studies have documented HHV-6 by PCR assay or culture in a majority (66% to 90%) of apparently asymptomatic adult lung transplant recipients.[327,386] Infections occur early after transplantation (median of 6 and 18 days) and can occur in the setting of CMV antiviral prophylaxis. Most are without obvious clinical manifestations that could be ascribed to HHV-6 alone.[559] HHV-6 DNA can be recovered from BAL fluid in 20 percent of lung transplant recipients and often is found with other pathogens, including other herpesviruses.[378] In immunocompromised patients, HHV-6 may exert direct and indirect effects on the host. It probably is responsible for rare cases of encephalitis, hepatitis, pneumonitis, febrile illnesses, and bone marrow suppression.[386] The presence of HHV-6 alone or as a cofactor to CMV may augment the immunomodulatory effects and increase the risk associated with fungal and other infections, as well as allograft rejection, bronchiolitis obliterans syndrome, and mortality.[327,378,450,490,559]

Many questions regarding HHV-6 in this population remain unanswered. PCR assay of peripheral blood lymphocytes is the most sensitive method for detection of virus, but it cannot differentiate between latent and active virus. Routine monitoring of asymptomatic patients is not recommended. Data are insufficient to recommend prophylactic or preemptive therapies, although the virus is susceptible to achievable levels of ganciclovir, foscarnet, and cidofovir. Treatment with these drugs may be considered in patients with compatible syndromes if other causes are eliminated.[559] Whether asymptomatic patients with documented HHV-6 infection would benefit from therapy with regard to the indirect effects of the virus remains unknown. Finally, HHV-6, unique in the herpesvirus family, can rarely be chromosomally integrated as a mechanism of latency (CIHHV-6).[674] It is estimated to occur in 0.8 percent of the normal population. Because the viral DNA integrates into every nucleated human cell, CIHHV-6 is characterized by extremely high viral loads (>1 million copies/mL blood), which may not indicate active infection. This has been described in solid-organ transplant recipients, although the significance of this occurrence is unclear.[382] Although some patients received antiviral therapy because of the concern of high titers, none had perceivable decline in their viral loads and those who did not receive therapy remained clinically asymptomatic. CIHHV-6 may lead to unnecessary antiviral therapy.

The role of HHV-7 and HHV-8 in solid-organ transplant recipients is undefined. HHV-7 behaves in a similar manner as HHV-6 in normal hosts, although it appears to be less prevalent and occurs later in life. Symptomatic disease is less well characterized, but it may be responsible for similar syndromes seen with HHV-6 in normal children and transplant recipients.[559] Evidence of HHV-8 infection in normal children is rare. Seroprevalence rates have wide geographic variation from 0 to 5 percent in North America to more than 50 percent in parts of Africa and thus may have increased relevance in transplant recipients from certain countries.[471] It is associated with Kaposi sarcoma in immunocompromised patients, as well as body cavity lymphomas, PTLD, and Castleman disease.[20,559] It also may be associated with fever and bone marrow suppressive syndromes of donor origin in transplant recipients.[409]

Community-Acquired Respiratory Viruses: Respiratory Syncytial Virus, Parainfluenza Virus, Human Metapneumovirus, Influenza, and Adenovirus

The paramyxoviruses respiratory syncytial virus (RSV), parainfluenza virus (PIV), and human metapneumovirus (hMPV) are common causes of upper and lower respiratory tract disease in normal children; symptoms range from congestion and rhinorrhea to laryngeal tracheobronchitis (croup), bronchiolitis, and pneumonia.[22-24] Similar clinical syndromes can be caused by a variety of viruses, and lung transplant recipients may have atypical presentation; thus testing should remain broad until a diagnosis is made.[324] Data on the impact of these viruses on lung transplant recipients are emerging. Respiratory viral illness is encountered commonly after pediatric lung transplantation and can be severe and persistent. Coinfection and sequential infection with other respiratory viruses, CMV, and fungal pathogens occurs.[40,237] A decreased 1-year survival was associated with respiratory viral illness, but not at 2 years in retrospective studies of

pediatric lung transplant recipients.[400,401] Neither study found an association with bronchiolitis obliterans syndrome, although others have.[347] Risk factors for respiratory viral illness included young age and CMV infection. Transmission occurs person to person, from exposure to infected nasopharyngeal secretions, and from fomites. Consideration should be given to screen recipients for incubating respiratory viruses before they undergo transplantation, especially if high levels of circulating virus are present in the community or illness is present in family members. Immunocompromised patients can shed infectious virus for long periods. Strict adherence to hospital infection control practices is most important in reducing nosocomially acquired disease from infected patients, visitors, and health care workers.[324] Patients and their families should be counseled on avoidance of exposure and on good hand washing practices when discharged from the hospital.

RSV can cause severe lower respiratory tract disease in lung transplant recipients. Although most infections resolve, with or without therapy, fatal cases have been reported, as have long-term declines in pulmonary function.[64,237,444,719] The diagnosis can be made from nasal washings by rapid antigen-detection kits, standard viral culture, or more rapid shell vial culture methods, although PCR-based assays, which provide sensitive detection of a broad range of viral pathogens, are now considered the preferred method.[324] Risk factors for poor outcome in immunocompromised patients include neutropenia, lymphopenia, age younger than 1 year, underlying lung disease, and augmented immunosuppression. High mortality rates in hematopoietic stem cell transplant recipients have led to prevention and treatment strategies that can serve as models for care in solid-organ transplant recipients,[176,238,727] although they are not without controversy.[64,241] Supportive care and reduction in immunosuppression remain the mainstay of therapy. For children with upper tract disease and risk factors or lower tract disease, aerosolized ribavirin should be considered. In addition, because outcomes, even in treated hematopoietic stem cell transplant recipients, are poor with ribavirin alone, some experts suggest combination therapy with RSV IVIG or monoclonal antibody (palivizumab) for immunocompromised patients with significant infections.[64,664] More recently, published reports using oral ribavirin, which is considerably easier and less expensive to use, suggest successful treatment.[391,536] Effective prophylaxis with palivizumab and RSV IVIG has been achieved in young infants with lung disease.[263,449] Care must be taken when extrapolating to other patient populations, given the unexpected poor outcomes of some infants with complex congenital heart disease who were administered RSV IVIG[611] but not pavilizumab.[204] Some experts would consider the use of immunoprophylaxis in young infants undergoing organ transplantation during the RSV season.[324]

hMPV was described in healthy young children in 2001.[684] It appears to have signs and symptoms similar to those of RSV, and almost universal infection probably occurs by 5 years of age.[733] The impact of hMPV on immunocompromised patients is as yet uncharacterized, in part because diagnostic tests have only recently become widely available. The virus can be cultured, but reverse transcriptase PCR appears to be the test of choice and is available as part of a PCR respiratory viral panel in most centers. Antigen assays are not yet available.[22] Studies on adult lung transplant recipients demonstrate that hMPV respiratory viral illnesses are common, often with coinfections and associated with graft dysfunction/acute rejection, but less likely than RSV infections to be associated with chronic graft rejection and bronchiolitis obliterans syndrome.[237,299,375,716] There is no established therapy for hMPV infections, outside of supportive care and treatment of co-pathogens, although ribavirin and IVIG are sometimes utilized.[299,324,723]

PIV (types 1 to 4) is isolated frequently as a cause of upper respiratory tract infections and croup in normal children.[23] PIV can cause severe lower tract infection in immunocompromised patients, including respiratory failure in lung transplant recipients, most notably caused by serotype 3.[33,694,697,720] Although rarely fatal in adults, persistent declines in pulmonary function and acute allograft rejection are important consequences of PIV infection.[444,694,720] A retrospective study on PIV in pediatric solid-organ transplant recipients (after liver, small bowel, lung, heart, kidney transplants) found significant age-related morbidity and mortality.[33] Although 44 percent of all patients with PIV infection had upper respiratory tract infections, only 11 percent of children younger than 1 year old had limited disease. A 16 percent mortality rate was associated with PIV, and predictors of mortality included age younger than 6 months, infection occurring less than 3 months after transplantation, and augmented immunosuppression. Infection in these children occurred in the context of community outbreaks. The diagnosis can be made by PCR assays and antigen detection; culture isolation can take weeks. Respiratory secretions obtained from nasal washings or BAL fluid can be used.[64] No proven therapy for PIV in lung transplant recipients is available. Intravenous and aerosolized ribavirin has been used in immunocompromised hosts, but without randomized controlled data or clear evidence of efficacy.[64,324,444]

Despite available immunoprophylaxis and chemoprophylaxis, influenza viruses A and B remain an important cause of morbidity in the normal population and lead to a considerable rate of mortality in the very young and the elderly.[21] In addition to the usual symptoms of acute onset of malaise, fever, myalgias, and respiratory symptoms, gastrointestinal symptoms also may be prominent.[227] Transplant recipients are at risk for acquiring community-acquired infection during the yearly epidemics, as well as nosocomial infection from visitors, hospital workers, and other transplant recipients as a result of infections occurring in the inpatient setting.[426,575,695] Seasonal influenza infection is relatively rare in solid-organ transplant recipients—4.2 percent of adult lung transplant recipients over the course of a 10-year period and 2.6 percent of pediatric solid-organ transplant recipients over a similar period[33,64]—but lung transplant recipients appear to be at a uniquely high risk for acquiring infection. In the adult study, the incidence was 41.8 cases per 1000

person-years for adult lung transplant recipients versus 2.8 and 4.3 per 1000 person-years in liver and kidney transplant recipients, respectively.[698] The authors speculate that optimal protection from influenza infection afforded by serum and secretory antibodies in the respiratory tract are altered in lung transplant recipients, thereby leading to higher attack rates. In addition, risk for disease and complications are high for pediatric transplant recipients in particular.[324] Previous data suggested that upper respiratory tract symptoms were the most common presentation of pediatric solid-organ transplant recipients with influenza, although 3 of 13 patients (23%) died.[33] In these children, corticosteroid bolus and OKT3 therapy given within a week of diagnosis of infection were associated with mortality. Transplant recipients may be at increased risk for acquiring secondary bacterial infections and nonpulmonary complications such as hepatitis, myocarditis, and aseptic meningitis.[64,698] Influenza was the causative agent in 8.9 percent of 101 respiratory viral illnesses documented in a series of pediatric lung transplant recipients observed between 1998 and 2007.[401]

Although we have an incomplete picture of the current epidemiology of influenza infections in pediatric lung transplant recipients, the H1N1 epidemic of 2009-2010 has added to our understanding of its impact. Risk factors for hospitalization and severe disease included age younger than 5 years and immunosuppression.[741] Two studies on adult lung transplant recipients suggest the majority of patients did well, but with a wide range of clinical impact from upper respiratory tract symptoms, association with progression to bronchiolitis obliterans syndrome, mechanical ventilation, and mortality (0%, 21%).[216,491] In a retrospective series of solid-organ transplant recipients (adults and children) with H1N1 infection, children were more likely to have fever, rhinorrhea, sore throat, and headache and less likely to have chest radiographic evidence of lower tract disease.[368] Of note, almost 50 percent of all patients had gastrointestinal complaints. In the pediatric cohort, mortality was 0 percent versus 7 percent in adults, with similar rates of admission (66%, 73%) and intensive care unit care (12%, 17.5%). Children were more likely to receive antiviral therapy within 48 hours.

Infection with the influenza virus is unique among respiratory virus infections in that both vaccine and chemoprophylactic strategies are available. Unfortunately, immunosuppressed patients may not respond well to influenza vaccine and, if disease is not recognized promptly, the effectiveness of therapy for established disease may not be optimal. Studies on the immunogenicity of influenza vaccine in pediatric solid-organ transplant recipients are more encouraging than in adult reports, which have documented poor response, especially when associated with mycophenolate mofetil or sirolimus.[94,281] In pediatric renal transplant recipients, response was similar to that of normal controls, without evidence of rejection,[196,225] although in pediatric heart transplant recipients protective antibody responses were not achieved until three doses of vaccine were administered.[8] No conclusive evidence documents a link between immunization and graft dysfunction with the intramuscular trivalent inactivated influenza vaccines, which have been used routinely for decades.[364] The current recommendation is that influenza vaccine be administered yearly to all solid-organ transplant recipients older than 6 months of age and 3 to 6 months after transplantation and to those awaiting transplantation, as well as to household contacts and caretakers.[21,94,364] During the 2009 H1N1 pandemic, recommendations for immunization were reduced to 1 month after transplant, with the acknowledgment that only partial protection was likely.[369] Children younger than 9 years of age receiving influenza vaccine for the first time should have two doses 4 weeks apart. The use of live attenuated influenza vaccine and intradermal and adjuvanted vaccines is not recommended. Oseltamivir chemoprophylaxis can be administered to patients who have not been vaccinated or who have not had sufficient time to respond to vaccination, especially if influenza is circulating in the community or if there is a known exposure. Dosing for young children and infants is now available.[325,343,369] Other agents approved for prophylaxis of influenza A in children older than 1 year include amantadine and rimantadine (M2 inhibitors), although resistance of influenza A is high and they are not active against influenza B strains.[21,695]

The diagnosis of influenza should be made by real-time PCR or other nucleic acid–based detection whenever possible. Multiplex PCR assays for respiratory viruses are now routinely available at most centers.[324,369] Rapid antigen testing is also available, but performance characteristics, especially during the 2009-2010 H1N1 pandemic, suggest this method is less reliable.*

Most experts would recommend empirical therapy with antiviral agents in a lung transplant recipient with suspected (community epidemic with compatible symptoms) or proven influenza, regardless of duration of symptoms (e.g., >48 hours).[64,326,365] During the 2009-2010 H1N1 pandemic, early therapy was associated with improved outcome (decreased hospitalization, intensive care unit, mortality) in high-risk patients as well as normal hosts.[368,741] The choice of agent depends on the type of virus (A or B) and information about resistance. The neuraminidase inhibitors oseltamivir and zanamivir are currently favored because of their broad spectrum of activity and less reported resistance.[324,695] Oseltamivir-resistant H1N1 retained susceptibility to zanamivir.[369] In addition, higher doses and prolonged therapy may be necessary, because the viral burden and length of shedding are increased in transplant recipients and children. Optimal length of therapy is not known; consideration for continuation of therapy until PCR testing is negative must be countered by the concern for emergence of viral resistance. Two intravenous antiviral agents, peramivir and zanamivir, as well as combination therapies are undergoing investigation and/or available for compassionate use from the FDA.[369] Choice of antiviral therapy should be made after consultation with the CDC and public health officials.

With improved management of herpesvirus infections and better diagnostic techniques, the impact of

*References 122, 137, 221, 240, 367, 371, 668.

adenoviral infections in transplant recipients is increasingly recognized. Adenoviral infections in solid-organ transplant recipients follow the epidemiology of infection in the general population, such that infections are more common in young pediatric than adult transplant recipients, who may remain naïve to many of the 52 recognized serotypes.[164,294,455,504] Other risk factors for infection include exposure to lytic antibodies, high levels of maintenance immunosuppression, and adenovirus serologic mismatch. Establishment of latency in lymphoid tissue has been documented, and numerous immune evasion genes have been identified.[294] Adenoviral infections have multiple putative sources, including the donor organ, reactivation from latency in host tissues, and infection acquired from the community or nosocomially.*

Infections in lung transplant recipients may be asymptomatic, lead to recognizable syndromes of the respiratory and/or gastrointestinal tracts, or cause disseminated disease, defined as involvement in two or more organs. Often disease is most pronounced in the allograft (e.g., pneumonitis, hepatitis, enteritis, hemorrhagic cystitis).[294] Cases of acute, disseminated, and fatal disease have been described in cardiothoracic transplant recipients. In lung transplant recipients, infections occur in the early post-transplant period and often cause disease in the graft in the form of necrotizing pneumonia.[86,504] Adenoviral infection has been associated with graft dysfunction, bronchiolitis obliterans syndrome, retransplantation, and death.[86]

Available diagnostic methods for the detection of adenovirus include culture, direct identification of antigens, and serology, as well as histologic examination of tissues for the presence of adenoviral inclusions and immunohistochemical staining.[126,294] Viral isolation by culture can be expedited by centrifugation in shell vial assays and immunofluorescent staining with adenoviral monoclonal antibodies, although viral serotyping cannot be done with this method. Direct identification of adenoviral antigens, usually performed on respiratory specimens, can be achieved by radioimmunoassay, immunofluorescence, or ELISA techniques, which are rapid and specific but less sensitive than culture.

Detection of virus with culture techniques and direct antigen detection are insensitive in identifying patients at risk for the development of disseminated disease. In addition, cultures may take a week or longer, and neither method may detect low levels of circulating virus. PCR assay has emerged as a powerful tool for detection of adenovirus in body fluids and tissues and for serotyping.† The virus's ability to establish latency can render interpreting the presence of virus or viral DNA in clinical specimens a challenge.[230,388] A single determination of the presence of adenovirus by PCR assay in immunocompromised patients may be nonspecific and perhaps misleading and should be correlated with histopathology if available and appropriate clinical syndromes to differentiate between asymptomatic infection and disease. As with other important viruses that establish latency, quantitative viral load patterns appear to be more informative with regard to the pathogenic role of adenovirus in these patient populations. No threshold has been identified to predict progression of infection or outcome. Studies in pediatric hematopoietic stem cell transplant recipients support the use of blood PCR surveillance as a method to identify patients at risk for disseminated disease.* Although routine surveillance is not recommended for lung transplant recipients, its use for early detection and monitoring in certain high-risk patients may be advocated.

The optimal therapy for adenovirus infection has not been determined. Supportive care and reduction of immunosuppression are the mainstays of therapy.[294] The role of immune recovery should not be underestimated, of which adenovirus-specific cytotoxic T cells are particularly critical.[114,284] Cidofovir, an acyclic nucleoside phosphonate, inhibits viral DNA polymerase with activity against all serotypes. It may be beneficial in severely ill patients with disseminated disease and rising viral loads.† Use of this agent may be associated with significant renal toxicity,[283,385,550] and use of modified dosing regimens has been investigated with some success.[106,295,481,705] CMX001 is an oral lipid ester of CDV with broad-spectrum antiviral activity that achieves very high intracellular antiviral activity and improved toxicity profile. It has been used for salvage therapy for severe adenoviral infection in immunocompromised patients and appears promising.[213] Strategies involving adoptive immunotherapy, such as infusion of adenovirus-specific cytotoxic lymphocytes that has been investigated in adenoviral infections in hematopoietic stem cell transplant recipients, may also be feasible,[206] with proof of concept for cytotoxic lymphocyte therapy published for solid-organ transplant recipients and EBV infections.[84,277,593]

Although a detailed discussion is beyond the scope of this chapter, the link between respiratory viruses and bronchiolitis obliterans syndrome or chronic allograft dysfunction should be addressed briefly. Bronchiolitis obliterans syndrome is a progressive condition, without good treatment options, and the greatest impediment to long-term survival for lung transplant recipients. It affects 50 percent of patients alive 5 years after transplantation and is the leading cause of death in adult and pediatric lung transplant recipients 1 year after transplantation.[677,714] Although the exact mechanisms are still being determined, the final common pathway is epithelial injury and intraluminal proliferation of fibroblasts, leading to airflow obstruction.[318,341,693] Stimulation of T cells and release of cytokines and chemokines by viruses are leading candidates for the initiation of these pathways. Many studies have linked viral infections, such as those caused by CMV, adenovirus, RSV, PIV, and others, often working in concert, to the development of bronchiolitis obliterans syndrome.‡ The role of these agents has yet to be proved, although it is biologically plausible.[318] Reduction of bronchiolitis obliterans syndrome remains an incentive for the continued development of preventive strategies against these viral infections.

Zoonoses and Donor-Derived Infections: Rabies, West Nile Virus, Lymphocytic Choriomeningitis Virus, and *Bordetella*

Isolation of unusual pathogens often is a sign of an unexpected exposure.[47,580] This statement is epitomized by the recent reports of solid-organ transplant recipients with uncommon zoonotic infections.[359] In the case of donor-derived rabies, lymphocytic choriomeningitis virus, and West Nile virus infections, multiple cases were traced to a donor or donors with retrospectively assessed exposures and risk factors.[207,287,326,643] West Nile virus in solid-organ transplant recipients also has been community acquired,[345,370] and cases of infection with *Bordetella bronchiseptica* in transplant recipients have been traced to sick pet dogs.[54,132,491] These cases are humbling in multiple respects. Many of these infections have no established therapy and, as expected, are associated with increased morbidity and mortality in solid-organ transplant recipients.[169,207,345,370,489] Therefore, prevention is of utmost importance. These cases advise us to counsel our post-transplant recipients on avoidance of potentially infectious exposures, such as travel, sick pets, and arthropod vectors of diseases.[357,365,489] Undeniably, they remind us of the almost limitless pathogens that may befall solid-organ transplant recipients, including those not yet described. These cases have newly informed the policies for reporting suspected donor transmitted conditions and opened a new dialogue on how screening procedures of organ and blood donors are conducted.*

CHAPTER 72

Opportunistic Infections in Liver and Intestinal Transplantation

Michael Green • Marian G. Michaels

Liver transplantation has been established as an effective treatment for children with end-stage liver disease for more than 25 years. Improving surgical techniques and the availability of new and more potent immunosuppressive regimens have led to enhanced survival rates, with 3-year survival rates approaching or exceeding 80 percent.[103] In response to these excellent results, more children are being referred for liver transplantation and increasing numbers of pediatric centers routinely perform this procedure. Intestinal transplantation, performed as an isolated procedure or in combination with the liver or other organs, has also gained expanded acceptance as a treatment for children with refractory intestinal failure with steadily improving survival rates over time.[103] This is particularly true for those children who experience progressive liver failure due to hyperalimentation-induced liver disease. Although this newer procedure has been routinely performed at only a limited number of centers, an increasing number of transplant programs are beginning to offer intestinal transplantation.

Infectious complications have been a significant cause of morbidity and mortality in children undergoing liver transplantation since this procedure gained its initial acceptance in the 1980s. However, improvements in the treatment options for, and management of, immune suppression along with the increasing availability of new antimicrobial agents and diagnostic tools have resulted in reductions in the impact of infectious complications on these children. Intestinal transplantation is associated with many of the same infectious complications seen after liver transplantation, as well as a number of infectious issues that appear to be unique to this procedure. Although development of increasingly effective treatment strategies for infectious complications is of great benefit to the children undergoing these procedures, emphasis has increasingly shifted to the development of strategies aimed at the prevention of infectious complications in children undergoing abdominal transplantation. A general overview of the problem of infections after liver and intestinal transplantation in children is presented in this chapter.

PREDISPOSING FACTORS

Liver and intestinal transplantation are associated with a set of technical and medical conditions that predispose to a unique set of infectious complications. The abdomen is a common site of infection in patients undergoing both of these procedures.[27,82] This is almost certainly due to the occurrence of local ischemic injury and bleeding, as well as potential soilage with contaminated material.[61] Additional factors predisposing to infection can be divided into those that exist before a transplant and those secondary to intraoperative and post-transplant activities.

Pretransplant Factors

The underlying illnesses leading to transplantation may be associated with intrinsic risk factors for infection. Some disorders may have required palliative surgery, which increases the technical difficulty of the transplant and may be associated with an enhanced risk for developing post-transplant infections.[23] For example, children undergoing liver transplantation for biliary atresia may have previously undergone a Kasai procedure (choledochojejunostomy), which may predispose to recurrent episodes of bacterial cholangitis before transplantation, increasing the likelihood of colonization with multidrug-resistant bacteria that can cause infection after transplantation. Similarly, children undergoing liver transplantation for cystic fibrosis may have an increased risk for developing invasive aspergillosis if they were colonized with this pathogen before transplantation. Complications of end-stage liver disease (as part of a primary liver disease or as a consequence of hyperalimentation in patients with intestinal insufficiency) may also predispose to infection after a transplant. A history of one or more episodes of spontaneous bacterial peritonitis before transplantation in patients with ascites has been associated with an increased rate of bacterial infections after liver transplantation[129] and could be expected in patients with liver disease associated with intestinal insufficiency. Finally, children undergoing intestinal transplantation experience frequent episodes of gastrointestinal-associated bloodstream infections. Recurrent exposure to antimicrobial agents to treat these episodes of bacteremia increases the likelihood of colonization and disease with multidrug-resistant bacterial and fungal pathogens after transplantation. Risks for bacterial translocation after intestinal transplantation with resultant bloodstream infection include the presence of a colon graft,[20] hospitalization before transplantation, and treatment with mycophenolate mofetil (MMF).[82]

Age, another important pretransplant factor, is a major determinant of susceptibility to certain pathogens, severity of expression of infection, and immune maturation.[1] Young children undergoing abdominal transplantation may experience moderate to severe infection with certain viral (e.g., respiratory syncytial virus [RSV]) or bacterial (coagulase-negative staphylococci) pathogens compared with more mild illness experienced by adult recipients infected with these pathogens. In contrast, certain pathogens, such as *Cryptococcus neoformans*, uncommonly manifest infection before young adulthood.[132] Age is also an important factor governing clinical expression of infection with cytomegalovirus (CMV) and Epstein-Barr virus (EBV). When transplants are performed in young patients there is a high likelihood that they will be seronegative for CMV and EBV and therefore susceptible to primary infections, which are more severe than infections due to reactivation.[10,62,105]

Donor-related issues represent another set of pretransplant factors. Transplant recipients are at risk for acquiring infections that may be active or latent within the donor at the time of organ harvesting. The most common examples of donor-associated infections are CMV and EBV. [9,11,18,105] Infections caused by CMV and EBV have been more severe after intestinal transplant compared with other organs. This may be because the intestine is an organ rich in lymphoid tissue, which may result in bringing a larger viral load of viruses from the donor compared with other graft types. Similarly, adenovirus has been isolated more commonly from pediatric recipients of intestinal transplants compared with other organs, which may also be related to donor transmission in the accompanying lymphoid tissue.[31,89,99] In contrast to CMV and EBV for which donor-derived transmission is expected, increasing attention has focused on the unexpected transmission of other pathogens such as human immunodeficiency virus (HIV), hepatitis B virus (HBV), and hepatitis C virus (HCV). Although the systematic use of donor screening has led to a decreased frequency of unexpected transmission of HIV, HBV, and HCV,[4,28,71] recent evidence now demonstrates donor-associated transmission of West Nile virus, rabies, as well as a number of other uncommonly transmitted pathogens.[70-72,121] Because organs from a single donor often go to disparate sites it is important for the recipient center to report back to the United Network for Organ Sharing (UNOS) any unusual infections that might possibly have come from the donor.

Intraoperative Factors

Operative factors unique to liver transplantation may predispose to infectious complications. For example, liver transplant recipients undergoing Roux-en-Y choledochoduodenostomy experience more infectious episodes than those who undergo a choledochocholedochostomy with T-tube drainage.[76,110] However, only the former option is usually performed in children undergoing liver transplantation because of the small size of their bile ducts. For combined liver-intestinal transplantation, evolution to en bloc replacement of the liver and intestine avoids the need for additional biliary anastomosis and minimizes the risk for infection related to biliary complications. Prolonged operative time (>12 hours) during the initial transplant has been associated with an increased risk for infection after transplant[38,76] and is likely a surrogate marker for the technical difficulty of the surgery. Intraoperative events, such as contamination of the operative field, also predispose to postoperative infections. Finally, the inability to close the abdomen after the transplantation due to size discrepancy or intraoperative complications appears to increase the risk for postoperative infections.

Post-Transplant Factors

Technical problems, immunosuppression, presence of indwelling cannulas, and nosocomial exposures are major postoperative risk factors for infectious complications. Thrombosis of the hepatic artery is the most serious technical problem after liver transplantation and predisposes to areas of necrotic liver and development of hepatic abscesses and bacteremia.[108,110] Bile duct strictures, developing as a sequelae of thrombosed hepatic artery and ischemia or due to technical difficulties, may predispose to cholangitis.[110] Retransplantation represents a high risk for intra-abdominal infection after intestinal transplantation.[82]

Immunosuppression is the critical postoperative factor predisposing to infection in all transplant recipients. Immunosuppressive regimens have evolved in an attempt to achieve more specific control of rejection with the least impairment of immunity. Thus, this evolution is aimed not only at improved control of rejection but also at decreased morbidity and mortality from infections. The use of cyclosporine-based regimens resulted in a decreased incidence of infections in renal and cardiac transplant recipients.[27,63,95] The introduction of tacrolimus has allowed many patients to be managed without corticosteroids.[51,127] Although reported rates of infection have been similar in liver transplant recipients treated with tacrolimus compared with those receiving cyclosporine, an apparent decrease in morbidity and mortality, especially from viral pathogens, has been noted with tacrolimus.[51] In contrast to these results, some centers have reported an increased rate of EBV-associated post-transplant lymphoproliferative disease (PTLD) in patients receiving tacrolimus.[22] However, data from the University of Pittsburgh suggests that the short and long-term incidence of EBV-associated PTLD appears to be similar in pediatric liver transplant recipients treated with either cyclosporine or tacrolimus.[14] More recently, induction immunotherapy has been used in combination with corticosteroid-free or corticosteroid-sparing immunosuppressive regimens whereas newer agents also are being explored. Potential infectious risks will need to be assessed for these and other evolving immunosuppressive regimens.

Children undergoing intestinal transplantation require an increased baseline level of immunosuppression compared with patients undergoing most other solid-organ transplant procedures.[105] With this increased level of immunosuppression has come an increased risk for development of infection. In an effort to overcome this, a

number of alternative immunosuppressive strategies have been explored. Looking at one such alternative strategy, Loinaz and colleagues found an increased risk for bacterial infections with both MMF and daclizumab after intestinal transplantation.[82] Another alternative approach evaluated the use of alemtuzumab induction in pediatric intestinal transplant recipients, which was associated with a marked increased incidence of EBV-associated post-transplant lymphoproliferative disease (PTLD) in one study[112] but not another.[73]

The treatment of rejection with additional or higher doses of immunosuppressant agents increases the risk for invasive and potentially fatal infection. Of particular concern is the use of antilymphocyte preparations, which are often indispensable in the management of corticosteroid-resistant rejection.[9,38,76]

The prolonged use of indwelling cannulas at any site is an important cause of infection throughout the post-operative course. The presence of central venous catheters is a cause of bacteremia after transplantation. This is particularly important for children undergoing intestinal transplantation where maintenance of long-term central venous access has been required for prolonged periods of time after transplantation.[34] The development of urinary tract infections and bacterial pneumonia are associated with the use of urethral catheters and prolonged nasotracheal or endotracheal intubation, respectively.[38,76]

Nosocomial exposures constitute the final group of postoperative risk factors in the hospital setting. Transplant recipients, especially children, may be exposed to many common viral pathogens (e.g., rotavirus, RSV, or influenza) while in hospital. Finally, the presence of resistant bacteria in the hospital increases the risk for nosocomial transmission and disease. Attention to infection control policies aimed at local epidemiology of circulating infections is paramount.

Finally, the presence in the hospital of heavy areas of contamination with pathogenic fungi, such as *Aspergillus*, may increase the risk for invasive fungal disease in these patients. The rate of fungal colonization increases during times of hospital construction. Infection control policies aimed at local epidemiology of circulating infections is paramount.

TABLE 72-1 **Differential Diagnosis of Infectious Complications During the Early Period (0 to 30 Days) After Pediatric Liver and Intestinal Transplantation**

Clinical Syndrome	Associated Pathogens
Wound infection	
Superficial	*Staphylococcus aureus* Enterococci
Deep	Enterobacteriaceae *Candida* spp.
Intra-abdominal infection	
Peritonitis	Enterobacteriaceae
Intra-abdominal abscess	Enterococci
Intrahepatic abscess (isolated liver and liver-intestine transplants) ± bacteremia	*Candida* spp.
Bloodstream infection, associated with:	
Central venous catheters	Coagulase-negative staphylococci Enterococci *S. aureus* *Candida* spp.
Hepatic artery thrombosis (isolated liver transplant only)	Enterobacteriaceae Enterococci *Candida* spp.
Intestinal rejection (intestine only)	Enterobacteriaceae Enterococci *Candida* spp.
Bacterial cholangitis (isolated liver transplant only)	Enterobacteriaceae Enterococci *Candida* spp.
Urinary tract infection	Enterobacteriaceae Enterococci *Candida* spp.
Ventilator-associated pneumonia	Enterobacteriaceae Enterococci *S. aureus*
Nosocomial acquisition of common community pathogens	Respiratory syncytial virus Parainfluenza virus Influenza virus Rotavirus
Noninfectious etiologies	Rejection Drug fever

TIMING OF INFECTIONS

The time of onset of infection with various pathogens after transplantation tends to be predictable. The majority of clinically important infections occur within the first 180 days after transplantation,[48,76] although infections continue to occur quite frequently beyond this time after intestinal transplantation.[73] The timing of infections can be divided into three intervals: early (0 to 30 days after transplantation), intermediate (30 to 180 days after transplantation), and late (>180 days after transplantation). In addition, some infections may occur throughout the postoperative course. These divisions should be viewed with flexibility because they may be modified by prophylaxis strategies and are somewhat less applicable to recipients of intestinal transplantation. Despite this, they remain useful, giving a general approach to a patient with fever after transplantation and can be used as a guide to differential diagnosis. An overview of the infectious complications occurring during each of these time periods is provided in Tables 72-1 through 72-3 and is summarized in the following sections.

Early Infections (0 to 30 Days) (Table 72-1)

Early infections tend to be associated with preexisting conditions and surgical manipulation. In general, they are caused by either bacteria or yeast. Bacterial infections are particularly common after intestinal transplantation, being reported in up to 90 percent of recipients.[82,125] As many as half of these early infectious complications may develop in the first 2 weeks after abdominal

TABLE 72-2 Differential Diagnosis of Infectious Complications During the Intermediate Period (31 to 180 Days) After Pediatric Liver and Intestinal Transplantation

Clinical Syndrome	Associated Pathogens
Viral syndrome	CMV
Fever, leukopenia, thrombocytopenia ± atypical lymphocytosis	EBV
Hepatitis	CMV EBV Adenovirus Hepatitis B Hepatitis C
Enteritis	CMV EBV Rotavirus Adenovirus *Clostridium difficile*
PTLD	EBV
Bacterial cholangitis*	Enterobacteriaceae Enterococci *Candida* spp.
Pneumonia	*Streptococcus pneumoniae* CMV Adenovirus RSV Parainfluenza virus Influenza virus Human metapneumovirus *Pneumocystis jiroveci* *Aspergillus fumigatus*
Bacteremia†	Enterobacteriaceae *Enterococcus* Coagulase-negative staphylococci (with central venous catheter) *Candida* spp.
Adenopathy	EBV/PTLD
Pulmonary nodules	EBV/PTLD *Aspergillus fumigatus*

*Typically only seen in isolated liver transplant recipients and usually associated with the presence of technical complication (e.g. biliary stricture).
†Seen in intestinal transplant recipients in association with presence of central venous catheters, intestinal rejection or PTLD involving intestine.
CMV, cytomegalovirus; EBV, Epstein-Barr virus; PTLD, post-transplant lymphoproliferative disease.

EBV, Epstein-Barr virus; PTLD, Post-transplant lymphoproliferative disease.

transplantation.[8] Cholangitis or spontaneous bacterial peritonitis presenting at or near the time of liver transplantation may lead to intra-abdominal infection after the transplant. Herpes simplex infection can also reactivate and cause early symptomatic disease,[76] although this is uncommon in children. Technical difficulties (e.g., thrombosis of the hepatic artery or portal vein and biliary strictures) predispose to early bacterial infections. Likewise, development of bile leaks and bowel perforations are associated with polymicrobial intra-abdominal infections, primarily consisting of enteric bacteria and *Candida* spp., in the first month after transplantation.[40] Early bacteremia is exceptionally common in intestinal transplant recipients and is usually associated with the presence of central venous catheters.[34] Likewise early bacteremia with gram-negative pathogens in these children has been associated with intestinal rejection.[34,43] Re-exploration of the abdomen is associated with increased rates of fungal infection.[76]

Intermediate Period (31 to 180 Days) (Table 72-2)

The intermediate period is the typical time of onset of infections associated with nonbacterial donor-associated transmission (either organ or blood products), reactivated viruses, and opportunistic infections. Without the use of prophylaxis, CMV peaks in incidence during this time.[9,76] The intermediate period is also when many patients begin to present with EBV-associated PTLD,[13,62] and *Pneumocystis jiroveci* (formerly *P. carinii*) pneumonia.[76] However, the use of prophylaxis against CMV and *P. jiroveci* can modify the time of presentation so that the occurrence of disease from these organisms may be after 180 days. Finally, bacteremia continues to be a frequent occurrence in pediatric intestinal transplant recipients with as many as 50 percent of all bloodstream infections occurring in this population being identified in this time period.[34]

Late Infections (Greater than 180 Days) (Table 72-3)

Late infections after abdominal transplantation are less well characterized than other periods because patients have usually been discharged from the transplant center

to their respective homes, which often are quite far away. This makes the accurate accumulation of data on these late infections difficult. Nonetheless, problems such as recurrent episodes of bacterial cholangitis in liver transplant recipients (typically associated with underlying problems of the biliary tree) and bacteremia associated with ongoing requirement for a central venous catheter, intestinal graft rejection, and/or PTLD in intestinal transplant recipients[34,82] continue to occur in this time period. In addition, children who are at high risk for CMV infection and have been kept on prophylaxis may delay the onset of CMV infection to the late period.[16]

Infections Occurring Throughout the Postoperative Course

Iatrogenic factors are an important cause of bacterial and fungal infections at all times but predominate in the early transplant period. Central venous lines are maintained for a variable time; the risk for infection persists for the entire period that the catheter remains in place. This is a particularly important problem for recipients of intestinal transplants who maintain central line access until the graft is fully functional. Similarly, the presence of urethral catheters and endotracheal tubes increases the risk for infections whenever they are in use.

Nosocomial acquisition of community viruses, such as RSV, rotavirus, and influenza A or B can occur at any time after transplant. These viruses spread easily in hospital environments from personnel or other hospitalized patients to transplant recipients. It is therefore important to modify diagnostic considerations according to local epidemiologic considerations.

BACTERIAL AND FUNGAL INFECTIONS

Bacterial and fungal pathogens are important causes of morbidity and occasional mortality in children undergoing liver and/or intestinal transplantation. With the exception of infections related to the use of indwelling catheters, sites of bacterial infection tend to occur at or near the transplanted organ. Accordingly, the intra-abdominal space is an important site of infection after any of the abdominal transplant procedures. Adding to the complexity of the management of bacterial infections in children undergoing abdominal transplantation is the fact that recovery of multidrug-resistant bacteria is increasingly common. Outbreaks of colonization and disease due to vancomycin-resistant *Enterococcus faecium* and extended-spectrum β-lactamase (ESBL)–producing *Klebsiella pneumoniae* have been reported among pediatric liver and intestinal transplant recipients.[42,44] These multidrug-resistant bacteria have been transmitted from patient to patient, prompting the imposition of strict infection control procedures. Reports of multidrug-resistant strains of *Enterobacter cloacae* associated with de-repression of a chromosomally located broad-spectrum β-lactamase enzyme have identified this very resistant organism as an important pathogen after liver transplantation.[19] Isolates of *E. cloacae* identified to also be carrying ESBL enzymes have also been recovered from intestinal transplant candidates and recipients, further limiting antimicrobial treatments. In some cases, effective antimicrobial agents may be unavailable to treat these complications. Knowledge of results of previous cultures and antimicrobial resistance patterns locally as well as from the home institution of the patient are critical components in choosing initial empirical antibiotic therapy for these patients to maximize their outcomes.

Liver Transplantation

Bacterial and fungal infections are a common early problem after liver transplantation.[21,59,64,131,137] Rates for bacterial infection of 40 to 70 percent have been reported from multiple series.[51,76,110] Bacteremia often occurs in association with intra-abdominal infection or with use of central venous catheters, but it can occur without an obvious source. Enteric gram-negative organisms account for more than one half of episodes. Bacterial infections involving the abdomen or surgical wound are common in most series. Infectious complications of the transplanted liver also occur. The most important complication is hepatic abscess, associated with hepatic artery or portal vein thrombosis, which often is accompanied by persistent bacteremia. However, the introduction of frequent surveillance Doppler studies early after transplant to monitor for development of thrombosis, coupled with the use of operative thrombectomy and thrombolysis, have essentially eliminated the development of hepatic abscesses in this population.

Ascending cholangitis is common after liver transplantation and is usually associated with biliary abnormalities. This diagnosis typically is made on clinical grounds in a patient with fever and biochemical evidence of biliary inflammation. Enteric gram-negative bacteria and enterococcal species predominate. However, this clinical picture can be identical to that of acute graft rejection; liver biopsy should be performed to differentiate these processes. A cholangiogram is performed to assess the status of the biliary tract for patients with proven cholangitis.

As many as 40 percent of children undergoing liver transplantation may develop a fungal infection during the first year following this procedure.[131] *Candida* spp. are the most common fungal pathogens, and infection usually is associated with an intra-abdominal focus or indwelling catheter. Infections due to *Candida* spp. are most commonly recognized in the first month after transplantation with candidal peritonitis most likely presenting in the first 2 weeks after liver transplantation in association with a bile leak or bowel perforation. Other risk factors associated with the development of candidal infection include prolonged duration of intubation after transplant, hepatic artery thrombosis, volume of blood transfused, and exposure to corticosteroids within the 3 months before the transplant. The recovery of *Candida* from a Jackson-Pratt drain in the early postoperative period may be the first indication of either of these two technical complications and may occur before the onset of clinical symptoms of intra-abdominal infection.[42] Accordingly, recovery of

Candida, alone or in combination with enteric bacteria, should prompt initiation of antimicrobial therapy and an aggressive evaluation for the presence of these complications. Early initiation of treatment is particularly important given an attributable mortality rate of up to 33 percent for candidal infections in pediatric liver transplant recipients.[42] The availability of fluconazole and echinocandin antifungal agents (e.g., caspofungin and micafungin) increases the number of therapeutic options for the treatment of candidal infections. However, acquired or inherent resistance to the azoles is an increasing concern, as are drug-drug interactions between azoles with both cyclosporine and tacrolimus and echinocandins with cyclosporine.

Episodes of invasive aspergillosis are uncommon but can be fatal.[52,56] Children undergoing liver transplantation for cystic fibrosis are at particular risk for developing infection due to *Aspergillus*.[130] Early disseminated disease in children with cystic fibrosis undergoing liver transplantation at Children's Hospital of Pittsburgh was observed in the early era of transplantation, prompting the use of perioperative antifungal prophylaxis in liver recipients with cystic fibrosis and a history of recovery of *Aspergillus* before transplant. Because data defining the precise duration of prophylaxis necessary to protect against this complication are not available, prophylactic treatment has ranged from 1 month of intravenous amphotericin to prolonged use of an oral azole agent (e.g., itraconazole or voriconazole). The availability of newer antifungal agents, including the advanced-generation azoles (voriconazole and posaconazole) as well as the echinocandins, has increased the number and complexity of therapeutic options for treatment of aspergillosis in children undergoing liver transplantation.[55] A summary of a suggested approach to the diagnosis and management of fungal infections after liver transplantation in children is provided in Table 72-4.

Intestinal Transplantation

Although increasing, the numbers of children having undergone intestinal transplantation remain relatively small. Many have received combined liver and intestine or multivisceral transplants. Bacterial infection occurs frequently in these patients.[43,116] One series reported that as many as 92 percent of children undergoing intestinal transplantation experienced an average of 2.9 episodes of bacterial infection per patient.[82] More than 80 percent of these patients experienced their first bacterial infection during the first 2 months after transplant. Bacteremia, which can be explained in part by disruption of the mucosal barrier associated with harvest injury or intestinal allograft rejection, is a common finding,[43,116] with one center reporting that 69 percent of pediatric intestinal transplant recipients experienced at least one episode of bloodstream infection.[34] Coagulase-negative staphylococci, enterococci, and gram-negative enteric bacilli account for most episodes. As noted earlier, antibiotic resistance is commonly seen in recovered pathogens. In the Children's Hospital of Pittsburgh experience, episodes of gut-associated bacteremia frequently secondarily infect central venous catheters, producing persistent positive cultures even after resolution of clinical symptoms. Accordingly, treatment strategies aimed at preserving the catheter (e.g., antibiotic lock therapy) may need to be used in combination with systemic antibiotics to accomplish a sustained clinical cure.[91]

Intra-abdominal and wound infections also are seen commonly in this population, occurring in more than one third of patients and are typically detected during the first month after transplantation. Gram-negative enteric pathogens, which frequently demonstrate multiple-antibiotic resistance as well as enterococci (often exhibiting vancomycin resistance) are the most common organisms associated with these complications. Recurrent laparotomies have been identified as a risk factor for intra-abdominal infection. One unique aspect of intestinal transplantation is the potential inability to achieve abdominal wall closure. Although failure to close the abdominal wall is an obvious risk for the development of intra-abdominal infection, the use of abdominal mesh as part of efforts to resolve difficult abdominal wall closures has also been associated with the development of superficial and deep wound infection.[26]

Another important site of infection is the intestine itself. *Clostridium difficile* enteritis can present as a pattern of fever, abdominal pain, and diarrhea that can easily be mistaken for graft rejection or viral infection due to CMV, EBV, and adenovirus. Accordingly, the diagnosis of *C. difficile* enteritis must be considered in any child in whom fever and changes in stool output are noted. In one small series, *C. difficile* enteritis was diagnosed in nearly 10 percent of children undergoing intestinal transplantation.[136] The frequent exposure to antibiotics and prolonged hospital stays that children undergoing intestinal transplantation experience are major risk factors for the development of this complication. Standard treatment with oral metronidazole is the recommended first-line therapy. However, use of prolonged therapy or oral vancomycin might be necessary for patients who experience relapse or recurrent episodes after primary treatment.

Invasive candidiasis and candidemia occur relatively frequently after intestinal transplantation in children, with one center reporting an incidence of approximately 23 percent in a series of 98 pediatric intestinal transplant recipients.[35] Candidemia accounted for 50 percent of the episodes of infection in this series, while nearly 40 percent involved the intra-abdominal space. Although the majority of episodes of candidemia infection occur in the first 3 to 6 months after transplant, later episodes may occur. Intra-abdominal infection with *Candida* is also observed, typically as part of a polymicrobial infection related to technical problems occurring during the initial transplant surgery or subsequent laparotomies. Specific risk factors associated with invasive candidiasis and candidemia include ongoing requirement for total parenteral nutrition and antibiotic treatment in the 7 days before diagnosis.[35]

Invasive mycoses due to fungal pathogens other than *Candida* are rarely observed. A recent report on fungal infections from the University of Nebraska identified four cases of invasive aspergillosis in 98 children undergoing intestinal transplantation,[32] whereas our experience at Children's Hospital of Pittsburgh has identified rare

*Common: >5%; uncommon 1-5%; rare <1%.
†Topical amphotericin B for bladder wash for noninvasive candiduria; ultrasonography of kidneys recommended to confirm absence of invasive disease.
‡Azole use must be accompanied by close follow-up of levels of cyclosporine or tacrolimus. In general, tacrolimus dosing should be cut in half when using a standard dose of fluconazole.
§Dose varies according to specific agent.
‖Fluconazole is alternative first-line drug for invasive disease if the species is known to be sensitive to fluconazole and the patient is clinically stable. Dosage is 6 to 12 mg/kg/day based on severity of infection.
¶Flucytosine should not be used alone but is synergistic when used in conjunction with amphotericin B. Dosage is 100 to 150 mg/kg/day divided every 6 hours.
**Radiographic staging includes computed tomography of head, chest, and abdomen.
††Itraconazole can be used long-term for patients who have been treated for invasive *Aspergillus* but in general is not recommended as first-line therapy.
‡‡Itraconazole absorption can be erratic. Accordingly, monitoring of itraconazole levels is recommended. Itraconazole is dosed at 3 to 5 mg/kg/day as a single dose. Dosing adjustment based on monitoring of levels is recommended. Adjustment of cyclosporine or tacrolimus dosing should be individualized.
§§The use of either of the approved echinocandins (caspofungin or micafungin) may be an appropriate alternative for treatment of invasive candidiasis, candidemia, and aspergillosis. Dose adjustments may be necessary in the presence of impaired liver function. Monitoring of tacrolimus levels are indicated because these agents may decrease tacrolimus levels.
‖‖‖Voriconazole levels should be checked for patients treated with oral therapy.
CSF, cerebrospinal fluid.

infections with *Aspergillus*, *Alternaria*, and *Scedosporium* in this population. In general, these children have been on high levels of immune suppression or have other complications such as PTLD and outcome of these infections has been poor. Guidelines for the diagnosis and management of fungal infection in children undergoing intestinal transplantation are provided in Table 72-4.

VIRAL INFECTIONS

Viral pathogens, especially herpesviruses, are a major source of morbidity and mortality after solid-organ transplantation. Patterns of disease associated with individual viral pathogens generally are similar among all transplant recipients. However, frequency, mode of presentation,

and relative severity can differ, according to the type of organ transplanted and the serologic status of the recipient.

Cytomegalovirus

CMV continues to be the most common and one of the most important viral pathogens after organ transplantation in children. CMV infection can be asymptomatic or symptomatic and may be due to primary infection (either from the donor graft or blood products), reactivation of latent infection, or superinfection with a different CMV strain in a previously seropositive child. Prior to the use of prophylaxis, the incidence of symptomatic CMV infection was reported to be as high as 22 percent in adult[56] and 40 percent in pediatric[9] liver transplant recipients. Use of ganciclovir prophylaxis or viral monitoring and preemptive treatment has resulted in a decreased rate and severity of CMV disease.[45] Intestinal transplantation was introduced after the availability of ganciclovir, and therefore has been able to take advantage of using ganciclovir both as prophylaxis as well as treatment. Despite this, it is clear that CMV disease can be very severe after intestinal transplantation and has a high rate of recurrence.[11,77] More recent reports identify decreased the incidence and severity of CMV disease in this population, although these patients continued to experience high recurrence rates of CMV infection.[33,85] Primary CMV infection, typically acquired from the donor organ (or passenger donor leukocytes that accompany the organ), is associated with the greatest degree of morbidity and mortality.[41,45] Accordingly, CMV-seronegative recipients of organs from CMV-seropositive donors are considered at high risk for developing CMV disease. Reactivation of, or superinfection with CMV, tends to result in milder illness after liver transplantation but can still be severe after intestinal transplantation.[10,12] CMV disease appears more likely to develop in CMV-seropositive recipients of CMV-seropositive donors than in seropositive recipients of seronegative donors.[41] Patients treated with unusually high doses of immunosuppressants, especially antilymphocyte antibody preparations, experience an increased rate of CMV disease regardless of previous immunity.[9,76]

Symptomatic CMV disease classically presented between 1 and 3 months after transplantation. It is important to note that the use of prophylactic or preemptive monitoring regimens may delay onset of CMV disease.[33] When present, a characteristic constellation of fever (which may be high grade, prolonged, and hectic) and hematologic abnormalities (including leukopenia, atypical lymphocytosis, and thrombocytopenia) is frequently seen. This "CMV syndrome" occurs in 25 to 50 percent of patients with symptomatic CMV infection. Invasive CMV disease is manifest by visceral organ involvement; common sites include the gastrointestinal tract, liver, and lungs. CMV hepatitis appears to be the most common site among liver transplant recipients whereas CMV enteritis is a frequent finding among intestinal transplant recipients. CMV chorioretinitis is rare in organ transplant recipients.

Diagnosis of CMV disease may be confirmed by detecting the presence of CMV DNA or pp65 antigen in the blood of a patient with a compatible clinical syndrome.[77,126] However, clinicians must be aware that results of viral cultures of the urine and even bronchoalveolar lavage specimens are difficult to interpret in previously infected patients because CMV is frequently shed asymptomatically in these secretions. Similarly, the presence of pp65 antigen and CMV DNA in the blood can be misleading, because these assays are often positive in asymptomatic patients. The specificity of this approach may be improved by quantitative determination of the pp65 antigen or CMV DNA. Because of the lack of specificity of these assays, histologic examination of involved organs to confirm the presence of CMV is critical when the diagnosis of invasive CMV is being entertained.

Antiviral agents with activity against CMV (e.g., ganciclovir, foscarnet, and cidofovir) have improved the survival of transplant recipients with CMV disease. Fatal, disseminated CMV disease occurred in 19 percent of infected children[9] and 5 percent of infected adults undergoing liver transplantation in the era before ganciclovir was introduced.[114] For clinical CMV disease, ganciclovir therapy is given in conjunction with reduction of immunosuppression unless evidence of rejection is present.[74] Clinical response usually occurs 5 to 7 days after initiation of therapy. Baseline immunosuppression levels are typically restored at the time of initial clinical response or on recognition of rejection. Data support the use of serial monitoring of CMV load in the peripheral blood as a guide to duration of treatment of CMV disease.[24,68,112] Valganciclovir was equally efficacious in treating adult kidney transplant recipients with CMV disease but not those who had undergone liver transplantation.[6] Controlled studies in children are lacking, but many centers use valganciclovir in children once they are discharged from the hospital. The role of CMV hyperimmune globulin in combination with ganciclovir in the treatment of CMV disease is controversial, although some evidence for improved outcome has been reported in the treatment of CMV pneumonia in adult liver transplant recipients.[39,68] Finally, because of the relatively high rates of nephrotoxicity associated with their use, foscarnet or cidofovir should be restricted to patients with apparent or proven resistance to ganciclovir, which should be suspected in patients who either fail to clinically improve or have persistent or rising CMV viral loads after 2 weeks of ganciclovir therapy.[68]

Historically, approximately 25 percent of patients treated with ganciclovir for an initial episode of symptomatic CMV will develop one or more episodes of recurrent CMV disease,[112,123] although rates of recurrent disease may have fallen in the presence of longer initial treatment and the use of secondary prophylaxis.[68] When present, recurrences are observed about 1 month after the initial infectious episode and may be associated with invasive disease. More commonly, however, these recurrent episodes tend to be milder than the initial episode. Risk factors identified with an increased risk for developing recurrent CMV disease include being a CMV-seronegative recipient of a CMV-seropositive donor, having disseminated CMV disease, and having a history of multiple treatment courses for rejection and persistent elevations of the CMV load at the end of therapy.[112]

TABLE 72-5 **Overview of Diagnosis and Management of Viral Infections After Liver and Intestinal Transplantation in Children**

	Cytomegalovirus	Epstein-Barr Virus	Respiratory Syncytial Virus	Influenza	Parainfluenza	Adenovirus
Frequency	Common*	Common	Uncommon	Uncommon	Uncommon	Liver: uncommon† Intestine: common*
Diagnostic Tests	Culture Quantitative CMV PCR (blood) pp65 Antigen Histology	Quantitative EBV PCR (blood) Histology Serology	NP aspirate for antigen detection or PCR	NP aspirate for antigen detection, PCR and/or culture	NP aspirate for culture or PCR	Viral culture or PCR Histology
Treatment						
Primary	Ganciclovir IV (5 mg/kg bid)	Decrease immune suppression	Supportive care	Supportive care	Supportive care	Decrease immune suppression
Secondary	Foscarnet§ Cidofovir§	Rituximab Cytoxan/ prednisone	Aerosolized ribavirin	Zanamivir Oseltamivir Amantadine Rimantadine		IV ribavirin
Adjunctive	Decrease immune suppression CMV-IVIG	Ganciclovir IVIG	Palivizumab Decrease immune suppression	Decrease immune suppression	Decrease immune suppression	IVIG§
Duration of Therapy	Site dependent	Individualized	Individualized	Individualized	Individualized	Individualized
Follow-up	Monitor quantitative CMV PCR or pp65 (treat until negative)	Monitor quantitative EBV PCR Repeat imaging studies if positive at outset	None	None	None	None

*Common: frequency ~>5%.
†Uncommon: frequency ~1-5%.
‡Rare: frequency <1%
§Foscarnet or cidofovir used for CMV infection when ganciclovir resistance is suspected or proven. Experience from HIV-infected patients suggests that a synergistic benefit will be obtained from the combined use of both of these agents when ganciclovir resistance is present.

Although current guidelines recommend continuing antiviral therapy until the CMV viral load becomes negative, further research is needed on duration.[68] A summary of our suggested approach to the diagnosis and management of CMV infection is provided in Table 72-5.

Epstein-Barr Virus

EBV infection, including EBV-associated PTLD, is an important cause of morbidity and mortality after liver transplantation and intestinal transplantation.* This is particularly true among children undergoing intestinal transplantation, who experience the highest rates of EBV-related disease than any of the other organ transplant recipients.[97]

Symptomatic EBV infection in general and PTLD in particular most commonly occur among transplant recipients experiencing primary EBV infection, particularly those who receive organs from seropositive donors. Accordingly, children undergoing transplantation are disproportionately affected by EBV compared with their adult counterparts.[53] As many as 80 percent of children who are EBV seronegative before liver transplantation will develop a primary EBV infection after this procedure.[117,120] Although primary infection occurs in the vast majority of seronegative patients, clinical disease develops in less than one third of these children.[117,120] In one study, 4 percent of children undergoing solid-organ transplantation and 10 percent of children with primary EBV infection developed PTLD between 1 month and 5 years after transplant[62]; 75 percent of cases occurred during the first postoperative year in patients undergoing cyclosporine-based immune suppression. Historically, cumulative occurrence rates reached as high as 12 to 20 percent by 7 to 12 years after pediatric liver transplantation.[83,94] Current rates of PTLD in this cohort appear lower, with an incidence of 4.7 percent at 5 years after transplant, likely owing to improvements in immune suppression and the use of preventive monitoring strategies.[103]

Pediatric recipients of intestinal transplantation appear to behave differently than children undergoing other types of organ transplantation in that the rate of EBV disease, including PTLD, occur irrespective of EBV

*References 3, 13, 62, 122, 128, 135.

serostatus before transplantation. Rates of EBV disease and PTLD after intestinal transplantation as high as 30 to 40 percent were reported during the initial experiences with intestinal transplantation. More recently, these rates have declined to approximately 11 percent,[85] reflecting improved immune suppression regimens and EBV-monitoring protocols. However, these rates still remain higher than those seen among other organ recipients.

A wide spectrum of EBV disease is recognized that includes nonspecific viral illness, mononucleosis, and PTLD (including lymphoma). Histologic evaluation is important in differentiating among these categories; manifestations can evolve in individual patients. Asymptomatic seroconversion also occurs. Variation in severity and extent of disease is related to the degree of immunosuppression and adequacy of the host immune response. Although EBV disease and PTLD may present as involvement of many different clinical sites, there is a tendency for EBV disease to involve the transplanted organ. Thus, EBV hepatitis and PTLD of the liver are observed more commonly among liver transplant recipients. Similarly, the intestine is the most frequently observed site of involvement of EBV disease among intestinal transplant recipients. Of interest, involvement of sites beyond the gastrointestinal tract is uncommon in intestinal transplant recipients.

Onset of viral syndrome, mononucleosis, and PTLD occur primarily within the first year, whereas lymphoma tends to present later. Immunosuppressive regimens based on the use of tacrolimus appear to have affected a shift in the timing of PTLD; only rare cases occur longer than 18 months after transplant.[15,135] This pattern of timing of EBV disease and PTLD appears to apply to all pediatric organ recipients, including children undergoing liver or intestinal transplantation. The impact of newer immunosuppressive agents and regimens on EBV disease needs to be constantly reevaluated because unexpectedly high rates of PTLD have occurred with some new regimens.[54,113]

The diagnosis of EBV-associated PTLD is made on the basis of clinical, laboratory, and histopathologic examination and should be suspected in patients with protracted fever, exudative tonsillitis, lymphadenopathy, organomegaly, leukopenia, or atypical lymphocytosis.[47,97] Gastrointestinal involvement should be suspected in patients with persistent fever and diarrhea. Accordingly, EBV must be considered in the differential diagnosis of rejection among intestinal transplant recipients. Serologic diagnosis is often confounded by the presence of passive antibody acquired at the time of transplantation or during subsequent transfusions. The detection of increased EBV viral load in peripheral blood identified by PCR has gained wide acceptance as an assay to predict risk for or presence of EBV or PTLD.[50,74,97,106,109] Although extremely sensitive, these assays are limited by both a lack of uniformity across different laboratories[101] and their lack of specificity; they are often elevated in asymptomatic patients.[1,2] Accordingly, every effort should be made to histologically confirm the diagnosis of EBV or PTLD. Occult sites of PTLD are assessed by performance of computed tomography of chest and abdomen. Palpable nodes or lesions (or both) identified by radiographic surveillance should be sampled. Endoscopic evaluation should be considered in patients with diarrheal illnesses and elevated viral loads.[17] Histologic evaluation for typical features may be augmented through the use of the Epstein-Barr–encoded RNA (EBER) probe.[104] The use of the EBER probe may be particularly useful in differentiating between the presence of rejection and EBV infection among intestinal transplant recipients.

Management of patients with PTLD is controversial.[15,48,97] Reduction of immunosuppression is recommended widely. Antiviral agents typically are used,[57,107] although their role has not been studied formally. Reduction of immunosuppression, alone or in combination with antiviral agents, results in an approximate 67 percent cure rate of EBV disease and PTLD. The potential impact of monoclonal antibodies,[30] interferon,[111] and chemotherapy[37] awaits formal clinical trials. Resection of tumor also may be of value for patients with lymphoma. Recent experience has focused on several novel approaches to the management of EBV disease and PTLD. These newer strategies have typically been used for patients who fail to respond to reduction of immune suppression (with or without the use of antiviral agents). Rituximab, an anti-CD20 antibody, has been increasingly used for the treatment of EBV disease. Experience to date suggests that as many as two thirds of patients who fail initial withdrawal of immunosuppression will respond to a 4-week course of this agent.[49] However, relapse of EBV disease has been observed in 20 to 25 percent of treated patients 6 to 8 months after completion of therapy at the time the rituximab is no longer present in the body. An alternate, chemotherapy-based approach for patients who fail to respond to initial reduction or withdrawal of immunosuppression has also been proposed.[56] This strategy, which uses modified doses of cyclophosphamide and prednisone, has also achieved success in approximately two thirds of treated patients. Unfortunately, as with rituximab, relapse of PTLD has been seen in 22 percent of treated patients and outright treatment failures have occurred in patients presenting with fulminant disease. Definitive studies comparing these two second-line therapies are needed to define the best option for those children who fail to respond to initial therapeutic modification of immunosuppression. A summary of our suggested approach and management of EBV/PTLD is provided in Table 72-5.

Other Herpesviruses

Other herpesviruses can also be hazardous after transplantation. Herpes simplex can reactivate early after surgery or after augmentation of immunosuppression. Prophylaxis with acyclovir (or ganciclovir) has been beneficial in these situations. A summary of the suggested approach to the diagnosis and management of HSV is provided in Table 72-5. Primary varicella infection (chickenpox) in transplant recipients can lead to disseminated, fatal disease[88] and should be treated early and aggressively with intravenous acyclovir. Some centers have used valacyclovir rather than intravenous medication, but further studies are needed. Reactivation disease

as shingles is more commonly seen in adults and can be prevented with antiviral prophylaxis early in the transplant period.

Interest has also focused on determining what role, if any, human herpesvirus–6 (HHV-6) and 7 (HHV-7) may play in causing disease in organ transplant recipients in general and abdominal transplant recipients in particular. Several groups of investigators have identified a potential interaction between the development of HHV-6 and HHV-7 and CMV infection in organ transplant recipients.[67,90] Reactivation of HHV-6 infection after liver transplantation has been associated with the development of an increased CMV viral load in the peripheral blood as well as a greater likelihood of developing symptomatic CMV disease.[67] In addition, it has been suggested that some or all of the symptoms typically associated with the CMV syndrome (e.g., fever, leukopenia) in patients with proven CMV infection may be attributable in part to HHV-6 or HHV-7. Studies in children have suggested that infection due to HHV-6 alone is a relatively common cause of unexplained fever in pediatric liver transplant recipients.[133,134] Interest also exists in the role, if any, that human herpesvirus–8 (HHV-8) may have in causing infection and disease in organ transplant recipients. This is particularly true for recipients who come from countries with moderate to high rates of HHV-8 prevalence such as Africa, the Middle East, and the Caribbean.[93] The full spectrum of disease of these more recently recognized herpesviruses and their potential therapies remain to be determined.

Adenovirus

Adenovirus has been reported to be the third most important virus affecting pediatric liver transplant recipients, occurring in 10 percent of one series of 484 children undergoing liver transplantation under cyclosporine-based immunosuppression.[92] Symptomatic disease (ranging from self-limited fever, gastroenteritis, or cystitis to devastating illness with necrotizing hepatitis or pneumonia) occurred in over 60 percent of infected patients. Infection was most commonly diagnosed within the first 3 months after transplantation.[46] The frequency of invasive adenovirus infection after pediatric liver transplantation appears to have decreased markedly with the use of tacrolimus-based immunosuppression.[51] In a more recent report, McLaughlin and colleagues found that only 4.2 percent of pediatric liver recipients using tacrolimus-based therapy had adenovirus disease.[89] This is in contrast to a significantly higher incidence of 20.8 percent of adenovirus infection in pediatric intestinal transplant recipients at the same institution. Florescu and colleagues reported a rate of adenovirus infection of 39 percent in their cohort of pediatric intestinal transplant recipients, although only 60 percent of infected patients were diagnosed to have adenovirus disease.[31] Finally, Pinchoff and colleagues found adenovirus in all 14 of their pediatric intestinal transplant recipients.[99] However, these exceptionally high rates might be attributable to the fact that viral cultures and PCRs were performed as part of routine screening of graft biopsies and not all of the patients were symptomatic. In all of these studies, high stool output, alone or in the presence of fever, was the most common sign found in these patients.

It is very difficult to presumptively diagnose infection due to adenovirus in pediatric abdominal transplant recipients, because fever, hepatitis, and pneumonia may be caused by a variety of other pathogens and high stool output after intestinal transplantation is nonspecific and can also occur with rejection. The presence of high-grade fevers and symptoms suggestive of adenovirus infection should prompt serial cultures for viruses (including adenovirus) or PCR investigation and evaluation of graft biopsies. Unexplained elevations in hepatocellular enzymes suggestive of hepatitis should warrant consideration of a liver biopsy. Similarly, an increase in stool output, with or without fever, should prompt endoscopic evaluation of the intestinal allograft. Histologic examination for the presence of adenoviral inclusions as well as the use of immunohistochemical stains of biopsies specimens from either site should be undertaken to help confirm this diagnosis.

Definitive evidence evaluating potential treatments for adenoviral disease is not available at this time. The most important component of therapy is supportive care along with a decrease in immunosuppression. The role of antiviral agents is unproven[7,46,49] but increasing data support the use of cidofovir in bone marrow or solid-organ transplant recipients.[45,58,105] Current available guidelines support consideration of use of this agent for patients with proven disease.[69] Ongoing studies are investigating the potential role of a lipid ester of cidofovir (CMX-001), which is currently in trial in bone marrow transplant recipients.[69] This drug, which is orally bioavailable, has been associated with less nephrotoxicity and may actually be more potent than the parent compound. Finally, a single case report also raised the possible role of intravenous immunoglobulin as treatment for adenovirus infection.[25] A summary of a suggested approach to the diagnosis and management of adenovirus infection is provided in Table 72-5.

Common Community-Acquired Viruses

Although the course of illness has been poorly documented, most children who undergo liver and intestinal transplantation experience the usual respiratory viruses and gastrointestinal illness without significant problems. However, infections due to influenza virus, parainfluenza virus, or RSV led to more severe disease in young children, especially if infection occurs soon after transplant and during periods of maximal immunosuppression.[5,29,71,100] Likewise, transplant recipients may have prolonged viral shedding even after resolution of symptoms. A summary of suggested strategies for the diagnosis and management of these community-acquired viruses can be found in Table 72-5.

Other Viruses

Other viruses, including both donor-associated viral infections (e.g., hepatitis B and hepatitis C virus) as well as community-acquired viral pathogens (e.g., enterovirus, rotavirus) are relatively uncommon causes of clinically

significant infection or disease after abdominal transplantation. Although this may be explained in part by the paucity of data describing infectious complications late after transplant, infection owing to these agents is clearly uncommon. For those patients for whom infection due to these pathogens is recognized, consultation with the primary transplant center is strongly recommended. Suggested approaches to the diagnosis and management of each of these viral pathogens are provided in Table 72-5.

OPPORTUNISTIC INFECTIONS

P. jiroveci is a well-documented cause of pneumonia in immunocompromised patients, including liver and intestinal transplant recipients. Prophylactic trimethoprim-sulfamethoxazole is safe, inexpensive, and effective.[65,66] The use of this strategy has eliminated *P. jiroveci* pneumonia in these patients at Children's Hospital of Pittsburgh, with rare breakthroughs occurring in patients who discontinued prophylaxis. Alternative prophylactic regimens for the sulfa-allergic patient include aerosolized pentamidine (for patients >5 years of age)[80] or dapsone.[69]

Tuberculosis (TB) is a particular concern in immunosuppressed hosts, including recipients of liver and intestinal transplantation. The incidence of TB after liver transplantation in Europe and the United States has been reported to range from 0.9 to 2.3 percent, with most reported cases in adults.[115,130] In contrast, up to 15 percent of organ transplant recipients in areas of high-level endemicity may develop TB.[115] However, development of TB after pediatric liver transplantation is extremely uncommon, with less than 20 cases reported to date.[86,115,130] To date, no cases have been reported among recipients of intestinal transplantation. Development of TB among solid-organ transplant recipients is associated with mortality rates ranging from 25 to 40 percent, with additional morbidity and mortality associated with development of rejection in patients receiving anti-TB therapy.[84,115,130] Diagnosis of TB in transplant recipients is complicated by the fact that extrapulmonary disease occurs frequently and purified protein derivative (PPD) testing is likely to be unreliable after transplant. Management of TB in liver transplant recipients is difficult both because of the side effects of anti-TB agents and their potential interactions with immunosuppressive agents.[115,130] Limited published experience in pediatric liver transplant recipients suggests that the majority of infections due to *Mycobacterium tuberculosis* are most likely due to a primary infection often associated with family contacts who have positive skin tests.[84,130] In contrast, experience with adult transplant recipients suggests that development of TB is more likely due to reactivation of latent TB.[60,115,130] Although only limited published information is available describing TB in these patients, transplant recipients known to have a positive PPD or who come from an area endemic for TB appear to be at increased risk for symptomatic reactivation after transplantation.[60,130] Similar data are not available for recipients of intestinal transplantation. Additional factors predisposing to the development of TB after transplantation include severe hepatic failure at the time of transplant, aggressive antirejection therapy, and/or concurrent HIV infection.[60,124] Experience among adult renal transplant recipients suggests that although the risk appears greatest in patients who received inadequate or no prior TB therapy,[81,84] it can also occur in patients who received appropriate anti-TB therapy in the pretransplant period.[81,84,102] Although TB has only rarely been encountered among pediatric liver transplant recipients,[130] and not among intestinal recipients, screening for TB by history and a PPD test along with review of a chest radiograph for lesions consistent with healed TB is highly recommended. Patients with a positive TB history and/or a positive PPD result should receive isoniazid for 6 to 12 months after transplant, although some experts recommend continuing this agent indefinitely while patients remain on immunosuppression. Attempts at a more definitive diagnosis are indicated for patients from endemic areas with a negative PPD result but suggestive chest radiograph. Careful evaluation for evidence of side effects, particularly hepatotoxicity, is recommended, and isoniazid is discontinued if unacceptable toxicity is identified.

Additional potential opportunistic infections include cryptococcosis, coccidioidomycosis, and histoplasmosis, although the pathogens of these infections have not been frequently reported among pediatric liver or intestinal transplant recipients. Prior infection with these pathogens is common in geographic areas where they are endemic. Because patients often travel to transplant centers distant to their homes, it is imperative that transplant physicians be aware of the local environmental risks for each patient. Experience with coccidioidomycosis in transplant recipients suggests that a minimum of 4 months of antifungal therapy, such as fluconazole, should be given in transplant recipients with this history.[56] Similarities between coccidioidomycosis and other fungal pathogens suggests that similar strategies may be necessary for patients with a positive history of prior fungal infection with pathogens known to recur after resolution of primary infection.

MANAGEMENT

Pretransplant Evaluation

A pretransplant evaluation is helpful in the management of infectious complications in liver and intestinal transplant recipients. A complete history and physical examination should be performed with particular attention to previous infections, immunizations, and drug allergies. Attention should be paid to a history of infection with multidrug-resistant bacteria, which may provide guidance for future empirical treatment that may be required after transplantation. An intermediate-strength tuberculin skin test should be performed on all patients. Alternatively, for children older than 5 five years of age, the interferon-γ release assays can be used.

The Children's Hospital of Pittsburgh pretransplant protocol includes obtaining serology for CMV, EBV, varicella, herpes simplex virus, hepatitis A, B (surface antibody, surface antigen, and core antibody), and C, and

HIV for all candidates. In addition, serology to measles, mumps, and rubella is obtained to ensure that the patients have a measurable antibody response to prior immunizations. Serologic tests on the donor should include HIV, hepatitis B and C, CMV, and EBV. Donors positive for HIV should be excluded whereas those positive for hepatitis B or C virus would be contraindicated except in the circumstance in which the recipient is also positive for hepatitis B or C, respectively. Knowledge of donor and recipient status for these viruses allows one to anticipate infection, identifying patients who might benefit from prophylactic regimens and guiding in the diagnostic evaluation of fever.

Prophylactic Regimens

Prophylactic regimens vary among transplant centers. These strategies have been divided into perioperative and long-term prophylaxis and often evolve to reflect the infectious complications seen at individual institutions.

Perioperative prophylaxis is used to prevent intraoperative sepsis and wound infection. It is based on individual patient characteristics and expected normal flora. At Children's Hospital of Pittsburgh, piperacillin-tazobactam is used as the standard agent for perioperative prophylaxis. This is modified if the recipient is known to harbor resistant bacteria. If sepsis is suspected in the donor, antibiotics are chosen to cover those organisms identified from the donor and treatment is usually extended to a therapeutic course of 10 to 14 days. In the absence of proven or suspected infection in the donor, perioperative prophylaxis is usually limited to the first 48 hours after transplant.

Considerations regarding long-term prophylaxis against infections occurring beyond the perioperative period include the risk and severity of infection as well as the toxicity, cost, and efficacy of a given prophylactic strategy. Nystatin is recommended for all pediatric transplant recipients in an effort to prevent oropharyngeal candidiasis until the patients are on less than 5 mg/day of prednisone. Trimethoprim-sulfamethoxazole is used to prevent *P. jiroveci* pneumonia. Although some centers recommend using trimethoprim-sulfamethoxazole for only the first 6 months after liver transplantation, anecdotal experience with patients presenting with PCP long after transplant and the relative safety of this agent have led us to recommend its use indefinitely after liver and intestinal transplantation in children.

The frequency and severity of CMV infection in transplant recipients prompts consideration of prophylactic strategies; optimizing the target population and timing of interventions require further study.[24,78] Potential roles exist for intravenous and oral ganciclovir[36] and oral valganciclovir.[96] Currently the Children's Hospital of Pittsburgh protocols use intravenous ganciclovir alone (for varying durations) for liver and low-risk intestinal transplant recipients (recipient CMV positive before transplant or donor and recipient seronegative) and ganciclovir plus intravenously administered immune globulin containing a high titer of antibody against CMV[118,119] for high-risk (donor CMV positive and recipient CMV negative) intestinal transplant recipients if available. At the present time, the use of oral valganciclovir is an alternative to prophylaxis with intravenous ganciclovir for adolescents, although the use of this medication is not approved for liver transplant recipients. This is because a higher rate of tissue invasive disease was observed in liver transplant recipients receiving valganciclovir compared with oral ganciclovir in the pivotal trial evaluating this agent. Nonetheless, published guidelines support the use of valganciclovir for adult liver transplant recipients.[68,98] Pharmacokinetic studies for dosing oral valganciclovir suspension in children after transplantation adjusted for body surface area and renal function suggest that ganciclovir exposures similar to those established as safe and effective in adults can be achieved.

Serial monitoring of blood CMV viral load using quantitative CMV PCR or the pp65 antigen assay as an indicator for the use of preemptive antiviral therapy has been proposed as an alternative to these chemoprophylactic and immunoprophylactic strategies.[47,68,75] In this approach, only patients demonstrating increased risk because of increased viral load are treated with intravenous or oral valganciclovir. Although this strategy has gained acceptance at some centers, experience in pediatric transplant recipients in general and in abdominal transplant recipients in particular remains limited. A combined hybrid strategy using viral load monitoring after completion of chemoprophylaxis is gaining increasing acceptance.[75]

Similar to CMV, there is an interest in the prevention of EBV infections and PTLD. A number of different strategies are used, including immunoprophylaxis, viral load monitoring, and preemptive therapy[49,87]; the efficacy of these approaches has not been established. The use of viral load monitoring to inform preemptive reductions in immunosuppression appears to be the most promising of these strategies.[3,79,87] Because reduction of immune suppression is not always possible for intestinal transplant recipients with a rising EBV load, preemptive use of intravenous ganciclovir and intravenous immune globulin has been used in addition to reduction of immune suppression (where possible) for this cohort of patients. Although prospective comparative data are not available, the use of this strategy appears to have resulted in decreased risk for disease and improved outcome compared with historical controls that were not followed with this strategy.[43] The use of anti-CD20 monoclonal therapy has also been used by some centers when decreased immunosuppression is not possible.

SUMMARY

Infections remain an important problem after liver and intestinal transplantation. Knowledge of the type, timing, and predisposing risk factors for these infectious complications allows for their timely and appropriate diagnosis and management.

CHAPTER 73

Opportunistic Infections in Kidney Transplantation

Gail J. Harrison

Renal transplantation is the therapy of choice for end-stage renal disease (ESRD) in children and adolescents.[154] It is successful in 90 percent of recipients and allows most children the best opportunities for normal growth and development and an almost normal lifestyle.[82,157,239] Despite the overall success of renal transplantation, infection remains the major cause of morbidity, graft loss, and mortality in renal transplant recipients.[57,99,150,232] Newer and more effective immunosuppressive regimens have reduced the rates and hospitalizations for graft rejection after renal transplantation, but rates and hospitalizations for bacterial and viral infections seem to be unchanged or increasing.[60,158,202] Prednisone-free maintenance immunosuppressive combinations with tacrolimus, mycophenolate mofetil, and sirolimus help maintain graft function, but they also may increase the risk for development of posttransplantation lymphoproliferative disorders (PTLD) and invasive fungal diseases.[116]

These infections can be managed successfully if detected early and treated appropriately.[116] In this chapter a general approach to renal transplant recipients is presented from the perspective of the infectious disease

specialist. Specific, detailed information regarding the diagnosis and management of each particular pathogen can be found in the respective chapters in the section of this textbook dedicated to infections with specific microorganisms.

PRETRANSPLANT EVALUATION

The role of the pediatric infectious disease specialist in the care of a renal transplant recipient ideally begins during the pretransplantation period.[185,186] Before the patient undergoes transplantation, a thorough history and physical examination should be performed, with a focus on evaluation for evidence of an active infection that may require immediate therapy or, rarely, preclude transplantation (Table 73-1). The history should be comprehensive but focus on the details of any history of previous infections that may reemerge during the posttransplant period, including urinary tract infections (UTIs); mucocutaneous diseases such as herpes simplex virus (HSV) infection; systemic illnesses such as tuberculosis; chronic infections such as those caused by hepatitis B virus (HBV), hepatitis C virus (HCV), or human immunodeficiency virus (HIV); and diarrheal diseases. Infection with HIV previously was regarded as a reason to exclude a potential recipient from undergoing renal transplantation. More recent successes with highly active antiretroviral therapy have improved long-term survival in HIV-infected pediatric patients, however, and have led clinicians, research scientists, and family members themselves to investigate the role of renal transplantation as a treatment for ESRD.[68,184]

TABLE 73-1 **Guidelines for Pretransplant Evaluation in Pediatric Kidney Transplant Candidates**

History
Past infectious diseases
Routine childhood illnesses
Travel to or birth or residence in areas endemic for fungal or parasitic diseases
Tuberculosis exposure
Animal exposure
Diet preferences and water resources
Vaccinations
Reactions or allergies to antimicrobial agents
Current or past immunosuppression
Physical Examination
Search for active or latent focus of infection
Nutritional status
Laboratory and Other Tests
Purified protein derivative
Chest radiograph
Urinalysis and urine culture
Viral serology for HSV, CMV, EBV, VZV, human erythrovirus (formerly human parvovirus B19), HAV, HBV, HCV, HIV, BK virus, WNV, and others depending on the history
Baseline HSV, CMV and EBV DNA PCR or CMV antigenemia, erythrovirus B19, HCV, BK virus if seropositive or posttransplant monitoring is anticipated
Fungal and parasitic testing if travel or exposure history positive; sputum or stool tests as indicated
Anticipatory Guidance
Update vaccines
Counsel regarding measures to reduce infection risk
Consider antimicrobial prophylaxis if at risk

CMV, cytomegalovirus; EBV, Epstein-Barr virus; HAV, hepatitis A virus; HBV, hepatitis B virus; HCV, hepatitis C virus; HIV, human immunodeficiency virus; HSV, herpes simplex virus; PCR, polymerase chain reaction; VZV, varicella-zoster virus; WNV, West Nile virus.

Renal transplant candidates undergo peritoneal dialysis or hemodialysis, so a history of previous dialysis catheter–associated infections should be documented and any current infection should be treated and eliminated before transplantation is performed. Another focus of the history should include an exposure history for the patient's country of origin or foreign travel, especially to areas endemic for organisms such as *Strongyloides stercoralis*, *Coccidioides immitis*, *Blastomyces dermatitidis*, or *Histoplasma capsulatum* and for diseases such as malaria and tuberculosis.[95,202] Other important exposures include blood product transfusions; exposure to animals or plants; well water as a source of drinking water; and dietary habits, especially consumption of raw or undercooked eggs or meat or unpasteurized dairy products.[185,186] Patients waiting for transplantation may become colonized with resistant organisms, including methicillin-resistant *Staphylococcus aureus*, vancomycin-resistant *Enterococcus*, gram-negative–resistant bacteria, fluconazole-resistant *Candida* species, and *Clostridium difficile*. In children who are unimmunized, a careful history of routine childhood illnesses, including varicella, measles, mumps, and rubella, should be documented.[119]

The immunization history of the patient should be documented carefully and, if needed or indicated, updated before the patient undergoes transplantation. Ideally, children with chronic renal disease should be fully immunized before progression to ESRD, for optimal immune response and protection during outbreaks of vaccine-preventable diseases.[47] Vaccinations against tetanus, pertussis, and diphtheria; polysaccharide vaccines, such as those against pneumococcus and *Haemophilus influenzae* type B; inactivated vaccines against polio and hepatitis A; and recombinant vaccines, such as those for hepatitis B, may be given or updated at any time before transplantation is performed.[33,226,238] Meningococcal vaccine is indicated routinely now for specific age groups and for special outbreak situations. The live varicella vaccine is recommended for renal transplant candidates who have not had varicella; it should be given at least 2 to 4 weeks before transplantation is performed.[257] The measles-mumps-rubella vaccine should be administered even earlier, preferably months before the patient undergoes transplantation. In addition, annual influenza vaccine and a tetanus booster every 10 years are recommended for patients who are renal transplant candidates or recipients.

If the child is unable to be fully immunized before undergoing transplantation, the routine immunization

schedule for the inactivated vaccines may be reinstituted after immunosuppression is decreased, which usually occurs 6 to 12 months after an uncomplicated transplant procedure.[33,226,238] Live virus vaccines should be avoided in the posttransplant period in most instances. Reports of safe and effective vaccination with varicella vaccine in selected posttransplant patients have been published, however.[31,39,79,178,179] Close contacts and family members of renal transplant candidates and recipients also should be fully immunized and should receive the annual influenza vaccine.[11] Other important points in the pretransplant evaluation history include allergies or reactions to medications, especially antibiotics, and the use of immunosuppressive agents.

Pretransplant laboratory and diagnostic imaging evaluations for most renal transplant candidates should include a chest radiograph, urinalysis, and urine culture for bacteria. Baseline renal and liver function tests also should be performed.

Serologic screening of the transplant recipient's status regarding organisms that may reactivate in the recipient or infect the recipient via the donor organ should be performed; such screening should include tests for HSV; cytomegalovirus (CMV); varicella-zoster virus (VZV); Epstein-Barr virus (EBV); human erythrovirus (formerly human parvovirus B19); *Treponema pallidum; Toxoplasma gondii;* hepatitis A, B, and C viruses; and HIV. Transplant recipients who are seropositive for HSV or CMV usually receive antiviral prophylaxis during the peritransplant period, whereas recipients seropositive for EBV may undergo posttransplant monitoring. It may be helpful to save an aliquot of the recipient's (and donor's) serum in case unusual circumstances occur, such as infection with West Nile virus (WNV). In CMV-seropositive transplant candidates, baseline CMV antigenemia or quantitative DNA polymerase chain reaction (PCR) may be useful; and in EBV-seropositive candidates, detection of EBV DNA by quantitative PCR may be helpful to document pretransplant viral load, especially if posttransplant virologic monitoring is to be performed.

Evaluation for active or latent tuberculosis infection should also be performed before the transplant. This evaluation should include a history of risk factors, including BCG vaccination, close contacts, and country of origin, and a chest radiograph. In addition, a tuberculin skin test (TST) and interferon-γ release assay (IGR) (QuantiFERON-TB gold, QuantiFERON-TB gold in tube, or T-SPOT.TB) should be performed. Positive IGR assay results predict subsequent development of tuberculosis in adult kidney transplant recipients in whom latent tuberculosis infection cannot be detected by TST.[124] General reviews of IGR assay results in adults with ESRD and in children also suggest IGR assays are useful, but caution should be used when interpreting IGR test results in young children, especially when results are discordant with TST.[41,204] The pretransplant evaluation also is an opportunity for the infectious disease specialist to counsel the patient and family about measures that may reduce the transplant recipient's risk for development of infectious disease complications after the transplant. Patients who have an exposure, or even a suspected exposure, to varicella (chickenpox) or zoster (shingles) should contact their physicians immediately to see whether passive immunoprophylaxis with varicella-zoster immunoglobulin or postexposure antiviral therapy with acyclovir or valacyclovir is indicated. Plans for foreign travel to remote areas also should be discussed with the physician. The transplant recipient should consume only thoroughly cooked meat and seafood and thoroughly washed fresh fruits and vegetables. In addition, drinking water should be pure. Transplant recipients should avoid, if possible, changing cat litter boxes, aquariums, and birdcages and should avoid close contact with people who have viral respiratory tract illnesses. Finally, medical attention should be sought if fever occurs, especially if it is significant or persistent.

POSTTRANSPLANT INFECTIOUS COMPLICATIONS

Infections occurring in the posttransplant period can be grouped into three main time frames: the first month post transplant (early), 2 to 6 months post transplant (middle), and 6 months post transplant and onward (late).[205,222] Although almost any organism or pathogen can infect a transplant recipient at any time, these time periods provide the clinician with a guide to the organisms and disease processes most commonly encountered (Table 73-2).

Infections Occurring During the Early Posttransplant Period

Infections occurring during the first month after renal transplantation has been performed usually are bacterial.[211] Common sites of early infections include the wound, urinary tract, lungs, and indwelling intravascular catheters.[191]

Wound Infections

As with any surgical procedure, wound infections may develop in a renal transplant recipient. They occur in approximately 2 percent of renal transplant recipients and range in severity from a superficial wound infection, easily treated with wound care and antimicrobial therapy, to deep perinephric abscesses that may be difficult to treat and result in transplant nephrectomy.[206,211] Wound infections are more likely to occur in patients with technical problems associated with the transplant surgery, including urinary leaks, vesicoureteral reflux, wound hematomas, or lymphoceles.[163,258] Malnutrition during the pretransplant period may impair wound healing and predispose the patient to development of wound infection.

Open Penrose drains may increase the likelihood of introducing microorganisms into the wound, whereas closed suction drainage, such as with a Jackson-Pratt drain, may reduce this risk. In addition, prompt removal of all drains, usually within 5 days in most uncomplicated cases, and administration of prophylaxis with perioperative antibiotics may decrease the incidence of wound infections; such measures are performed routinely in most renal transplant centers. The regimen usually is

TABLE 73-2 Timetable for the Occurrence of Common Infections and Usual Pathogens After Kidney Transplantation

Early Period
Wound infections
Urinary tract infection
Bacteremia and sepsis syndrome
Pneumonia
Herpes simplex virus
Hepatitis B virus

aimed at uropathogens and staphylococci. One dose generally is given before the transplant, and the regimen is continued for only 24 hours after the transplant.

The diagnosis of a wound infection should be suspected if erythema, warmth, or discharge is present at the wound site or if an unexplained fever develops. Fluid may drain from the wound persistently, or a fluid collection or abscess may be seen on imaging of the deeper operative sites. The patient will be receiving immunosuppressive agents, however, and the findings may be unusual or the symptoms may be blunted. Any fluid or pus obtained should be stained and cultured for bacterial, mycobacterial, and fungal organisms. Organisms most likely to be identified as causes of wound infection include staphylococci (*Staphylococcus aureus*, especially methicillin-resistant *S. aureus*, but also coagulase-negative staphylococci), streptococci, and gram-negative enteric organisms. Unusual, multidrug-resistant, or health care–associated bacterial pathogens and yeast, such as *Candida albicans*, also may cause wound infections after the transplant. In addition, case reports of wound and perinephric fluid collections infected with *Mycoplasma hominis* have been published.[224]

Appropriate antimicrobial therapy, initially broad-spectrum and then ultimately tailored to the isolated organism and its susceptibility pattern, should be administered. The duration of appropriate antimicrobial therapy usually is 10 to 14 days, or until the wound infection has resolved and the patient has been afebrile for 3 to 5 days. Deep abscesses or unusual organisms may require longer therapy.

Urinary Tract Infections

UTIs are common developments after renal transplantation and may affect 35 to 79 percent of renal transplant recipients.[129,258] Posttransplant UTIs are associated with acute and chronic graft dysfunction and may threaten renal graft survival.* They may occur during the early, middle, or late posttransplant period and should be differentiated as afebrile and febrile.[116] A UTI that is febrile and occurs during the early or early/middle posttransplant period often is a severe illness complicated by pyelonephritis, urosepsis, metastatic foci of infection, allograft dysfunction, rejection, and relapse.[169,207] UTIs occurring in the early posttransplant period are associated more often with graft loss than are UTIs that occur later.[55]

The risk for developing an invasive UTI after undergoing renal transplantation seems to be increased in patients with prolonged bladder catheterization (most catheters can be removed during the first few days after transplant), dysfunctional bladder, ureterovesical disorders with reflux, malnutrition, underlying disorders, renal stones, obstructive uropathy, or a contaminated cadaveric kidney.[2,185] The inability of the bladder to empty completely or surgical complications, such as hematoma, reflux, or obstruction at the urinary anastomosis, are associated with UTIs. In addition, young infants, especially infants who have vesicoureteral reflux, seem to have a high incidence of complicated UTIs after a transplant procedure.[169] Procedures that address the etiology and correct underlying physiologic and anatomic abnormalities of the bladder and ureters should be performed before transplantation to avoid or lessen development of complications associated with these problems.[2,14,35,231] Newer surgical techniques allow children with reconstructed bladders to undergo successful renal transplantation with minimal risk for posttransplant development of UTIs.[163,207]

The organisms most commonly isolated from patients with early-onset UTIs include not only the typical

*References 2, 14, 35, 55, 118, 167, 231.

gram-negative enteric bacteria but also enterococci, staphylococci, and *Pseudomonas aeruginosa*. Unusual organisms, such as *Streptococcus mitis*, *Serratia marcescens*, and *Corynebacterium urealyticum*, also can be found. Antimicrobial therapy should be tailored to the susceptibility pattern of the organism isolated from the urine. Because 30 percent of patients experiencing a UTI during the early posttransplant period may have recurrent UTIs, a prolonged 6-week course of antibiotics usually is recommended to reduce the risk for developing a relapsing kidney infection.[163,207] Antimicrobial prophylaxis may reduce the risk for developing a UTI. Trimethoprim-sulfamethoxazole administered for the first 4 months after renal transplantation is effective in preventing most UTIs and can provide cross-cover prophylaxis against *Pneumocystis jiroveci* pneumonia and other diseases.[77]

Pneumonia

Pneumonia can occur during the first month after renal transplantation and often is associated with prolonged endotracheal intubation. Gram-positive and gram-negative bacterial pathogens acquired from normal oropharyngeal flora and unusual or health care–associated multidrug-resistant organisms predominate during the early posttransplant period.[186] *Legionella pneumophila* and unusual *Legionella* spp., such as *L. micdadei*, *L. bozemanae*, and *L. dumoffii*, also have caused outbreaks of serious, life-threatening pneumonia in transplant recipients in some centers.[34,45,128,186] *P. jiroveci* can cause pneumonia in a transplant recipient during the early posttransplant period, but more often it is associated with disease after the first month post transplant.[98] Rare or unusual pathogens, such as *Rhodococcus equi*, may cause pneumonia in these patients.[142]

Patients with pneumonia usually have fever, chills, chest pain, malaise, change in tracheal secretions, cough, dyspnea, tachypnea, change in ventilatory status, rales or rhonchi on auscultation of the lungs, and pulmonary infiltrates evident on a chest radiograph. Pneumonia may be complicated by pleural effusion, empyema, or pulmonary abscess, and death may occur if pneumonia is severe and not diagnosed and treated promptly. Treatment with antibiotics effective against the bacterial pathogens isolated from culture of tracheal aspirates, bronchoalveolar lavage fluid, or lung tissue is appropriate.

Bacteremia, Fungemia, and Sepsis

Bacteremia, fungemia, and sepsis occurring during the early posttransplant period often are associated with indwelling catheters.[184] The urinary tract, surgical wound, or transplanted or native kidney also may be a source.[153] Usual bacterial organisms such as coagulase-negative staphylococci or *S. aureus*, unusual bacterial organisms, and yeasts such as *C. albicans* and other *Candida* spp. may be involved. *Listeria monocytogenes* also may cause primary bacteremia or sepsis at any time after a kidney transplantation has been performed, but the greatest risk occurs during the early period. Complications include meningitis, and 10 percent of these patients may die.[166,217] Renal transplant recipients also are at increased risk for development of bacteremia with *Salmonella* nontyphoidal species.[53,110,184]

Complications such as UTI, graft infection, peritonitis, abscesses, and meningitis can occur, and recurrences are common. Therapy for bacteremia, sepsis, or its complications is tailored to the susceptibility pattern of the organism isolated from the patient's blood. The duration of therapy for uncomplicated bacteremia usually is 10 to 14 days, but a longer course of treatment may be indicated if abscesses occur or an unusual organism is isolated. Removal of the indwelling catheter may be necessary to clear persistent bacteremia, and abscesses and other foci of infection should be drained.

Other Bacterial Diseases

Pediatric renal transplant recipients also seem to be at increased risk for development of antibiotic-associated colitis caused by *Clostridium difficile*.[250] Infection of a lymphocele with *Pasteurella multocida* has been reported, as has systemic infection with *Bartonella henselae*.[3,43,59,146,184] A high index of suspicion always must be maintained when evaluating a transplant recipient for infection because the immunosuppression required to maintain the transplanted kidney predisposes the recipient to development of infection with unusual organisms.

Viral Infections

Herpes Simplex Virus. HSV is the most common virus encountered during the early posttransplant period, although antiviral prophylaxis significantly reduces the risk for development of this infection.[64,65] It occurs less frequently in pediatric (8%) than in adult renal transplant recipients (30%).[184,185] Most HSV infections encountered post transplant are due to reactivation of the recipient's strain; however, primary or recurrent infection acquired from the renal allograft may occur and primary infection from person-to-person transmission has been documented.[64,184,185,207]

Posttransplant HSV infection may be asymptomatic or associated with disease, most frequently oral ulcers in pediatric patients.[91] Genital and perianal ulcers may occur in adolescents and adults. Rarely, HSV may cause disseminated cutaneous lesions or zosteriform eruptions. HSV esophagitis may be manifested as dysphagia, refusal to eat, irritability, and substernal chest pain, and it may complicate oral HSV disease, especially if the oral mucosa has been traumatized by orogastric or nasogastric tubes. Acute, severe hepatitis with hepatic necrosis, often accompanied by hypotension and disseminated intravascular coagulation, also can occur. Tracheobronchitis and pneumonitis may occur as a result of HSV, primarily in patients with pneumonia caused by another pathogen and whose mucosa has been traumatized by endotracheal intubation. It is often severe and life threatening, even with appropriate supportive care and antiviral therapy.[184] Encephalitis also has been reported in renal transplant recipients.[87]

The diagnosis is made by isolation of HSV in cell culture or detection of viral antigen by immunofluorescence or viral DNA by PCR in the end-organ involved.

Detection or isolation of HSV in body secretions may represent asymptomatic shedding or disease and should be correlated clinically. If HSV DNA by PCR is detected in blood, viremia is likely present and should be treated. Treatment with acyclovir is recommended for patients with mucocutaneous lesions, viremia, or end-organ disease, and HSV-seropositive transplant recipients should receive acyclovir or valacyclovir prophylaxis during the peritransplant period to prevent development of HSV infection. Most patients receiving ganciclovir, valganciclovir, foscarnet, or cidofovir for CMV prophylaxis also are protected against HSV.

Other Viruses. Seasonal viruses, especially winter respiratory viruses such as respiratory syncytial virus, influenza viruses, parainfluenza viruses, and adenoviruses; winter diarrhea viruses, such as rotavirus; and late summer/early fall viruses, such as the enteroviruses, can infect the transplant recipient during the early posttransplant period and cause disease. Such infections may be acquired from the family or the community, or they may occur from health care–associated exposures. Transplant recipients who may not be adequately protected by routine vaccination are at risk for severe influenza and its complications. In 2012, results of a study on oseltamivir prophylaxis with once-daily dosing for 12 weeks during periods of local influenza circulation showed that it was well tolerated and reduced influenza in adult and pediatric kidney and other solid-organ transplant recipients.[113] Oseltamivir-resistant influenza A was detected during the study period.[113]

Renal transplant recipients who are chronically infected with HBV or HCV may experience liver dysfunction during the early transplant period, but the late posttransplant period, beyond the first year, carries the greatest risk for progression of liver disease to cirrhosis. If a renal transplant recipient acquires HBV soon after undergoing transplantation, acute hepatitis can develop, often with death from liver failure.[52,184]

Noninfectious Causes of Fever

The most common noninfectious cause of fever in the first posttransplant month is allograft rejection.[206] Fever often is the first sign of rejection, especially in children, and rejection should be considered if an infectious source of the fever is not identified. Another common noninfectious cause of fever early after transplantation is antilymphocyte antibody therapy (OKT3). The first two or three doses of OKT3 produce a release of cytokines, which cause fever and chills. In most patients, these symptoms resolve after the third dose. Other noninfectious causes of fever during this period include drug reactions and pulmonary emboli.

Infections Occurring During the Middle Posttransplant Period

The cumulative effects of immunosuppression begin to be revealed during the period 2 to 6 months after transplantation. If a significant amount of antirejection therapy is required for multiple episodes of rejection, the effects may be more pronounced. Such immunosuppression allows classic opportunistic pathogens, such as CMV, *P. jiroveci*, *Toxoplasma gondii*, *L. monocytogenes*, *Aspergillus*, and *Nocardia*, to evade immune surveillance and cause disease.[98,184,249,251] Reactivation of organisms previously infecting the transplant recipient or the donor allograft, including *Mycobacterium tuberculosis*, HBV, HCV, HIV, *H. capsulatum*, and *C. immitis*, also may cause disease. In addition, an occult bacterial focus of infection that was not adequately identified and treated before the transplant may become apparent at this time and cause significant disease.[206]

Herpesviruses

The Herpesviridae (HSV types 1 and 2, CMV, EBV, VZV, and human herpesvirus [HHV] types 6, 7, and 8) share the biologic properties of latency, reactivation, cell association, and oncogenicity, which renders them the most important group of pathogens that affect renal transplant recipients.[184,212] HSV is more important during the early posttransplant period, whereas the other herpesviruses are important causes of morbidity and mortality during the middle and late posttransplant periods.[99]

Cytomegalovirus. CMV may cause primary infection in a CMV-seronegative transplant recipient through a renal allograft or blood product transfusion from a seropositive donor.[20,51,203] Person-to-person transmission within the family or close community also is possible. Recurrent CMV infection develops in seropositive transplant recipients if the recipient's CMV strain becomes reactivated. The renal allograft from a seropositive donor also can be a source of reinfection to the recipient and produce active CMV infection or disease.[42,92] CMV infection in renal transplant recipients may cause silent or asymptomatic infection; end-organ diseases such as hepatitis, esophagitis, colitis, encephalitis, vasculitis, and retinitis; and systematic disease with persistent fever and leukopenia. A case report also linked CMV infection with posttransplant occurrence of atypical hemolytic-uremic syndrome that resolved with plasma exchange and ganciclovir antiviral therapy.[177] It has been linked in some studies to allograft dysfunction and nephropathy.

CMV also causes depressed cell-mediated immunity and impaired alveolar macrophage function, rendering the host more vulnerable to other opportunistic infections, such as fungal disease and *P. jiroveci* pneumonia, and it serves as a cofactor for other viruses, such as EBV and HHV-6 and HHV-7.[123,180,192,234,235] In addition, CMV is associated with acute and chronic rejection and allograft nephropathy and decreased long-term patient survival.[1,66,134,184,203]

Disease caused by CMV can be documented by isolation of CMV from blood or tissue; detection of CMV antigen pp65 in circulating leukocytes; or detection of CMV DNA by PCR or similar assays in blood, bronchoalveolar fluid, or tissue.[26,27,188,193,203] Isolation of CMV in urine or saliva documents active infection but has little significance in predicting disease; serologic tests may document seroconversion in primary infections but generally should be reserved for pretransplant screening

only. Most transplant patients at risk for acquiring CMV disease (i.e., CMV-seropositive recipients [D^+/R^+] or CMV-seronegative recipients [D^+/R^-] who received a renal allograft from a seropositive donor) should be monitored by viral surveillance, usually by testing blood weekly for CMV antigen pp65 or for quantitative CMV DNA by PCR.[25,104]

Detection of significant levels of the virus by quantitative or semiquantitative assay, or an increase from baseline levels, usually predicts CMV disease.[235] Reduction of immunosuppression, along with preemptive antiviral therapy, generally is indicated and results in a decrease or resolution of CMV levels detected in blood.* Despite receiving adequate antiviral therapy, some patients have persistently positive CMV DNA by PCR, however, which should be interpreted within the clinical context.[26] In some patients who otherwise appear well, the DNA may be fragmented and nonreplicating, whereas in other patients with persistent symptoms, a strain of CMV resistant to one or more antiviral agents may be the cause.

The antiviral agents currently available for the treatment of CMV disease and preemptive therapy for positive CMV markers include ganciclovir, valganciclovir, foscarnet, and cidofovir.[248] For renal transplant patients with moderate to severe CMV-associated disease, 2 to 3 weeks of therapy with intravenous ganciclovir usually is adequate to treat disease; however, patients with CMV retinitis or repeat episodes of rejection may require maintenance therapy, usually with oral valganciclovir.[111,148,170] Asymptomatic or mild CMV infections may respond to oral valganciclovir administered for 1 to 3 months.[148,164] Preemptive therapy should be continued throughout the period of immunosuppression in patients who are severely immunosuppressed and at risk for development of CMV disease and recurrence (D^+/R^-).[89,104,149,164] Foscarnet and cidofovir have significant renal toxicity and should be used with caution in renal transplant recipients. Prophylaxis for CMV disease is indicated in high-risk transplant recipients (D^+/R^-); options include intravenous CMV immune globulin and oral valganciclovir.†

Epstein-Barr Virus. EBV infection in children who have received a renal transplant may be asymptomatic or may be associated with a variety of different syndromes, including a nonspecific viral syndrome, mononucleosis, smooth muscle tumors (leiomyoma), post-transplant PTLD, and lymphoma.‡ Infection and disease may occur after primary and recurrent EBV infection, but primary infection is more likely to occur and produce PTLD in younger children than in adults who have received solid-organ transplants.[35,96] EBV disease may affect 10 percent of pediatric renal transplant recipients and may develop 1 month to 5 or more years post transplant, with the risk accumulating every year of post-transplant survival. Recurrence of post-transplant PTLD may also occur years after transplant and may involve unusual sites.[13,57,218]

Knowledge about post-transplant EBV infection and disease is evolving; as graft survival has improved, with more intense immunosuppressive regimens that preserve graft function, and other opportunistic infections such as HSV, CMV, and *P. jiroveci* being successfully managed, EBV has emerged as a formidable obstacle to successful solid-organ transplantation in children.* The estimated overall risk for development of serious life-threatening EBV-associated illness is at least 4 percent and increases to 10 percent in children who experience a primary infection with EBV after undergoing renal transplantation.[56,106] Other risk factors for PTLD in children who have received solid-organ transplants include receipt of antilymphocyte therapy such as OKT3 for rejection; receipt of tacrolimus, sirolimus, or mycophenolate mofetil, rather than cyclosporine, for immunosuppression; and CMV or EBV donor/recipient (D^+/R^-) mismatch.[58,115,116]

Nonspecific viral syndromes and mononucleosis occur during the earlier posttransplant period, whereas lymphoma and leiomyoma are more likely to be a manifestation during the late posttransplant period.[30,61,78,94] Uncomplicated posttransplant mononucleosis is characterized by the self-limited illness of fever, pharyngitis, cervical adenopathy, and splenomegaly. The signs and symptoms of PTLD vary but often include persistent fever, weight loss, and generalized adenopathy.[106] The disease frequently is multisystemic and progressive, and involvement of the neck, chest, lungs, gastrointestinal tract, liver, spleen, eyes, and brain, as well as lesions, may be detected by computed tomography of the head, neck, chest, and abdomen.[4,5,185,213] The renal allograft also may be involved and show dysfunction. Lymphoma may be manifested as solid tumors in the renal allograft, lung, liver, spleen, brain, and soft tissues.[78,96] Smooth muscle tumors (leiomyoma) frequently are multicentric and multifocal; they often occur in lung, liver, and spleen but also may occur in unusual locations, including the brain and renal allograft.[28,94,105]

Laboratory diagnosis of posttransplant, EBV-associated disease is based on detection by PCR of EBV DNA in circulating lymphocytes.[5,49,70] Quantitative or semiquantitative PCR assays may show increasing or persistently high copies of EBV DNA in the circulating lymphocytes of patients who are at risk for developing PTLD.[5,93,201] If end-organ disease is observed, the diagnosis can be confirmed histopathologically by detection by PCR of EBV DNA in tissue or by in situ hybridization with an EBV-encoded RNA probe.[4,235]

The diseases associated with EBV also may be classified in the laboratory as polyclonal or monoclonal. Polyclonal illnesses seem to be more benign than are monoclonal diseases, which often are associated with chromosomal abnormalities and malignant transformation.[185] The virus cannot be cultivated by routine means; when studied by special culture techniques, EBV has been found frequently in the oropharyngeal secretions of seropositive transplant recipients and is not predictive of EBV-associated disease.[185,201] Similarly, serologic approaches to establishing the diagnosis of EBV infection after a transplant procedure also are nonspecific and difficult to interpret in most patients, unless the recipient

*References 7, 27, 46, 49, 85, 89, 143.
†References 30, 74, 85, 137, 170, 216, 223, 244.

*References 28, 56, 58, 61, 94, 121, 218.

clearly has seroconverted during the posttransplant period.

Aggressive or intense treatment of uncomplicated EBV-associated viral syndrome or mononucleosis usually is unnecessary because these illnesses seem to be self-limited in most patients. Immunosuppression may be reduced, and acyclovir may be administered; the patient should be monitored carefully. If symptoms in the patient or EBV DNA levels in the blood persist or increase, PTLD should be suspected and the diagnosis should be confirmed.[229,236]

Treatment of established PTLD is challenging.[90] Mortality rates are high, and the best results seem to occur if the disease is diagnosed by quantitative PCR viral-load monitoring and serial imaging studies and treated aggressively.[235] Preemptive therapy instituted when viral surveillance monitoring detects an increase in EBV DNA in circulating lymphocytes before end-organ disease is evident also may be helpful in some patients.[4,49,148] Reduction in immunosuppression remains the most widely recommended strategy, but a variety of regimens have been studied as well.

Antiviral agents such as acyclovir and ganciclovir seem to reduce EBV replication early in the course of the disease process and may halt the progression of disease in some patients.[58,186,248] Antiviral agents are ineffective, however, against latent EBV or cells that have been transformed by the virus. Interferon-α, immunoglobulin, and anti–CD20 monoclonal antibody preparations such as rituximab have been used successfully in patients with established PTLD. Experimental protocols evaluating adoptive immunotherapy in transplant recipients are ongoing. In addition, some experts suggest that administration of intense anti-CMV therapy with ganciclovir and CMV hyperimmune globulin may improve chances of survival in certain patients with PTLD because CMV may serve as a cofactor in progression of disease caused by other members of the Herpesviridae.* Treatment of patients with lymphoma or leiomyoma includes a reduction in immunosuppression, chemotherapy, radiation therapy, and surgical resection of tumors.

Varicella-Zoster Virus. VZV can cause primary (varicella, chickenpox) or reactivation (zoster, shingles) disease in a renal transplant recipient.[185,222] Infection with VZV can occur at any time but does so most often during the middle posttransplant period. Patients have fever and painful or pruritic vesicular skin lesions.[170] Hepatitis, encephalitis, acute or chronic recurrent cerebral vasculitis and vasculopathy, and pneumonia also may occur, even in the absence of skin lesions, especially in an immunocompromised host.[107] Varicella occurs more frequently in children, and zoster occurs more frequently in adolescent and adult transplant recipients.[40]

In contrast to other herpesviruses, VZV almost always is transmitted person to person or by aerosol in health care, family, and community settings; it rarely, if ever, has been linked to the transplanted allograft.[156,185] Before the advent of routine immunization and antiviral therapy, infection with VZV was a major cause of morbidity and mortality in children receiving solid-organ transplants.[40,72,207] Untreated primary varicella may continue for several weeks and result in visceral dissemination, pneumonitis, hepatic necrosis, encephalitis, vasculitis with stroke, disseminated intravascular coagulation, hemorrhagic skin lesions, and death.[72,186,212] Zoster in solid-organ transplant recipients may remain localized to a dermatome, but it often disseminates beyond the dermatomal distribution and produces widespread skin lesions and even visceral dissemination.

The diagnosis of VZV disease often is clinical, but it should be confirmed by isolation of VZV from fresh, vesicular skin lesions or detection of viral antigen by direct immunofluorescence assay on cells obtained by scraping the base of the skin lesion.[186] Tzanck smear may show multinucleated giant cells, suggesting a viral infection, but it cannot differentiate VZV from HSV. Other pathogens, especially HSV, may mimic VZV disease, so establishing an accurate viral diagnosis is important. VZV also may be detected by PCR-based DNA detection methods, which also may distinguish wild-type strains from the OKA vaccine strain of VZV; qualitative and quantitative VZV PCR tests may be performed by reference and research laboratories. Establishing a serologic diagnosis of active VZV infection is difficult. Routine serologic screening performed in the pretransplant period identifies patients who are seronegative and at risk for developing primary infection with VZV.

Treatment of established VZV disease should be instituted as early as possible during the course of the illness because survival is improved if treatment begins before the fifth day of illness.[72] Acyclovir is recommended for most renal transplant recipients experiencing either primary infection with varicella or zoster with dissemination; it is administered intravenously in high doses (500 mg/m^2 per dose every 8 hours if renal function is normal or adjusted for renal function as needed) for 5 to 10 days, or until new lesions have ceased to occur for 24 to 48 hours, old lesions have crusted, the fever has resolved, and disease has abated.[31,178,185,248] Uncomplicated zoster or very mild primary varicella may be treated with oral acyclovir, famciclovir, or valacyclovir, provided that the patient is monitored carefully for clinical response. Ganciclovir, foscarnet, or cidofovir also provide cross-cover protection for most VZV strains, if these antiviral agents are being administered for difficult CMV infections. If acyclovir-resistant varicella develops, then treatment with foscarnet or a combination of two or three antiviral agents may be necessary to control the infection.

Prevention of posttransplant VZV disease can be accomplished by several effective strategies, which should be discussed during the pretransplant evaluation. Transplant recipients who were seronegative for VZV during the pretransplant evaluation should receive varicella vaccine before undergoing transplantation, if possible.[79,125,257] Pretransplant varicella vaccination is safe, beneficial, and cost effective when administered to pediatric renal transplant candidates and in selected renal transplant recipients after a transplant procedure.[31,39,79,80,178]

Seronegative, unimmunized transplant recipients who are exposed to varicella or zoster during the posttransplant period should receive passive immunoprophylaxis with varicella-zoster immunoglobulin (VariZig).

*References 1, 20, 61, 189, 221, 234.

Preemptive therapy with oral acyclovir also is recommended by some experts in this situation because varicella-zoster immunoglobulin does not prevent, but only attenuates, the postexposure disease process. Finally, acyclovir, valacyclovir, ganciclovir, and valganciclovir administered prophylactically to transplant recipients who are seropositive for HSV or CMV also may provide protection against VZV disease.[137,185]

Human Herpesviruses Types 6, 7, and 8. HHV-6, HHV-7, and HHV-8 also infect renal transplant recipients by primary infection and by reactivation.* Infection with these viruses becomes evident during the middle posttransplant period, but their roles in specific disease processes are unclear.[186,215,230] HHV-6 and HHV-7 may act as cofactors in the progression of a disease, especially diseases caused by CMV and EBV.[69,123,170,180,234] HHV-8 is associated with Kaposi sarcoma after a transplant procedure in severely immunosuppressed adult renal transplant recipients, but to date it has not been appreciated as a major opportunistic pathogen in pediatric renal transplant recipients.† HHV-8 may be transmitted through the renal allograft or by blood product transfusion, or it can become reactivated in the recipient after transplant surgery.[198]

Polyomaviruses and Papillomaviruses

Polyomaviruses. Human polyomaviruses (JC, BK, and SV40) frequently infect children and are present in urine and stool.[242,243] They can be detected in the urine of 33 to 58 percent of renal transplant recipients and detected serologically in 56 percent, and they are found histopathologically and by PCR in blood, body fluids, and tissue in 8 to 13 percent.‡ Knowledge about the roles that these viruses play in the outcome of renal transplant patients is evolving.

The JC and BK polyomaviruses seem to have a significant impact on adult and pediatric renal transplant recipients.§ BK virus has been implicated in various syndromes, including ureteral stenosis, hemorrhagic or chronic cystitis, interstitial nephritis with graft failure, allograft nephropathy (BK-associated nephropathy [BKAN]), and rejection, in renal transplant recipients.|| Disease associated with these viruses most often occurs during the middle and late post-transplant periods. BK virus may be asymptomatic or cause increasing serum creatinine levels, cystitis, tubular necrosis, graft dysfunction, or allograft rejection.[181,196] Risk factors for BKAN seem to include BK serostatus at the time of transplant, greater immunosuppression with use of mycophenolate mofetil, and concurrent CMV infection.¶

Ciprofloxacin prophylaxis in kidney transplant recipients has been shown in one recent study to reduce BK virus infection and BKAN 3 months post transplant, but not at 1 year post transplant.[252] BK virus historically was detected in urine by the presence of "decoy cells," which are cells containing intranuclear viral inclusions. Currently, quantitative PCR assays that detect and quantify BK viral DNA are used for detection. BK viruria precedes BK viremia, which precedes BK nephropathy.[15,103] Patients with BK-associated nephropathy may have BK viral DNA detected in the urine, blood, or plasma, and renal biopsy specimens may show characteristic viral inclusions. Most recently, quantitative PCR viral surveillance in blood or plasma has been shown in renal transplant recipients to be useful in predicting the development of BK nephropathy and in guiding preemptive antiviral and immunosuppressive strategies.

Pediatric kidney transplant recipients who have increasing BK viremia levels should be managed preemptively with carefully monitored reduction of immunosuppression to prevent development of more serious complications of BKAN and graft rejection.[194] This strategy usually results in reduction and then clearance of BK viremia and development of BK-specific cellular immunity coincident with BK virus clearance.[140] Treatment of established BKAN includes a reduction in immunosuppression. Cidofovir and fluoroquinolones have activity against BK virus, and both have been used to treat BK virus infection and treat severe disease caused by BKAN.[103,248] Intravenous immune globulin may also be of benefit; one report resulted in decrease of BK viremia and histologic resolution of BKAN.[8]

JC virus causes a rare syndrome called *progressive multifocal leukoencephalopathy*. It may be diagnosed by viral DNA detection using PCR-based assays available in reference and research laboratories or histopathologically by brain biopsy or autopsy examination. Successful treatment options for progressive multifocal leukoencephalopathy caused by JC virus are very limited, and most, if not all, patients die of progressive encephalopathy.

Papillomaviruses. Human papillomaviruses are common viruses that infect healthy children, adolescents, and adults. Adult renal transplant recipients are at increased risk for development of human papillomavirus–associated disease, such as cervical cancer and anogenital papillomas, whereas pediatric patients may develop numerous disfiguring warts post transplant, especially if they require severe immunosuppression.[175,185,200] Malignant transformation of cutaneous warts caused by high-risk types has been documented.[200] Treatment options are limited but include physical removal of papillomas with laser and cryotherapy and careful reduction of immunosuppression. Information on the use of human papillomavirus vaccines in patients with ESRD or renal transplant recipients has not been published.

Adenoviruses

Adenoviruses may infect pediatric renal transplant recipients at any time, but they are most likely to cause significant disease during the middle posttransplant period. They continue to emerge as a significant pathogen in pediatrics, including transplant recipients. They do not seem to play as important a role in renal transplant

outcome, however, as do other viruses, such as the herpesviruses, and they currently are not as prominent in renal transplant recipients as they are in other transplant recipients, such as recipients of liver, lung, bone marrow, or stem cell transplants.[88,152,176,185,186] Nonetheless, infections with adenoviruses in pediatric renal transplant recipients, when they occur, can be serious and include hemorrhagic cystitis, diarrhea, allograft nephropathy, pneumonia, hepatitis, and disseminated disease with multisystemic involvement.*

The diagnosis is made by isolation or detection by PCR of the virus in respiratory secretions, stool, urine, blood, or tissue. Rapid diagnosis may be accomplished within 30 to 60 minutes, using a rapid immunochromatographic assay that detects adenovirus antigens in eye secretions, respiratory samples, urine, and stool. Viral DNA also may be detected by PCR or quantitative PCR available in reference or research laboratories, and characteristic changes may be seen by histopathology in tissue. Adenovirus serotyping by neutralization assays and genotyping by PCR sequence-based assays are available in reference laboratories.[88] Treatment of serious adenoviral disease primarily is supportive. Immunosuppression also may be reduced, when possible. Antiviral agents, such as ribavirin, ganciclovir, and cidofovir, have activity against adenoviruses. Clinical reports of use of cidofovir in traditional weekly dosing and intermittent renal sparing dosing is safe and well tolerated in pediatric transplant recipients with adenovirus disease.[21,36,62]

Human Erythrovirus

Human erythrovirus (formerly human parvovirus B19) has been reported to cause acute and chronic infection, manifesting as chronic anemia, red blood cell aplasia, and pancytopenia in renal transplant recipients.† It also has been implicated in collapsing glomerulopathy and thrombotic microangiopathy in renal transplant recipients.[246] Unusual manifestations, such as hepatic necrosis or central nervous system infection with vasculitis, also have been reported.[19,22,131,132] Transmission most likely is person to person; however, some reports indicate that the virus may be transmitted by blood product transfusion or in the renal allograft.[18,19,130] More recent reports suggest that the role that this virus plays in the outcome of renal transplant recipients may be more important than previously recognized, but systemic studies in pediatric patients have not been done.[18]

The diagnosis of acute infection with human erythrovirus is supported by erythrovirus-specific IgG seroconversion; detection of erythrovirus-specific IgM antibodies in serum; or detection of viral DNA in plasma, blood, body fluids, bone marrow, or tissue. The virus is not cultivatable in clinical virology laboratories that use routine cell cultures, but laboratories using special erythroid precursor cell lines may be able to cultivate erythrovirus for research purposes. No specific antiviral therapy is available, but anecdotal experience and case reports support a beneficial role for intravenous immunoglobulin and carefully monitored reduction in immunosuppression as management strategies to resolve erythrovirus viremia and associated end-organ disease.[159]

West Nile Virus

WNV is a single-stranded RNA flavivirus that has emerged as an important pathogen worldwide. It usually is transmitted by mosquitoes and causes a febrile illness, viral meningoencephalomyelitis, and acute flaccid paralysis in the normal host. Renal transplant recipients may become infected with WNV that is transmitted by the organ donor, by blood product transfusions, or naturally from mosquitoes.* Routine screening of solid-organ donors for WNV infection has been discussed but currently is not routinely performed.[112,168] Infection with WNV may manifest in the early posttransplant period if it is transmitted by the graft or blood products and, because of immunosuppression, produce severe febrile illnesses, seizures with status epilepticus, encephalitis, paralysis, and movement disorders. Death also may occur.[50] A high index of suspicion is required; and if WNV is suspected, serum and cerebrospinal fluid should be sent for WNV-specific IgG and IgM antibody testing. The virus also may be isolated in special cell cultures and detected by reverse transcriptase PCR-based assays. Immunohistochemical staining may show WNV proteins in tissues from biopsy or autopsy examination. Outcome in renal transplant recipients with WNV disease improves with early establishment of the diagnosis and carefully managed reduction of immunosuppression.[197]

Mycoplasma

Mycoplasma spp. commonly infect school-aged children. Children and adolescents who undergo renal transplantation also may experience respiratory tract infections with *M. pneumoniae* and *M. hominis*. The infection also may disseminate to extrapulmonary sites, causing hepatitis, septic arthritis, or perinephric fluid collections in pediatric renal transplant recipients.[120,151,224] *Mycoplasma* spp. may be detected using special biphasic culture media or PCR-based assays. Serologic diagnosis is difficult to accomplish, owing to cross-reactivity of antigens producing the possibility of false-positive reactions in some patients. Antimicrobial therapy with macrolide antibiotics, along with carefully managed reduction of immunosuppression, may be beneficial in selected patients.[120,151]

Bacterial and Mycobacterial Diseases

Bacteria that commonly produce disease in renal transplant recipients during the middle posttransplant period include *L. monocytogenes*, which often causes sepsis or meningitis.[185,217] Routine bacterial illnesses that were not identified and properly treated during the pretransplant period also may emerge at this time and cause abscesses, sepsis syndrome, and death.

*References 24, 122, 206, 232, 241, 251, 254.
†References 10, 18, 19, 22, 131, 139, 141, 145, 159, 182, 227, 246, 253.
*References 50, 112, 114, 126, 197, 245.

Mycobacterial disease caused by *M. tuberculosis* may occur at any time after transplantation, but it occurs most frequently during the middle posttransplant period.[135,138,185,195] *M. tuberculosis* causes disease in approximately 1 percent of renal transplant recipients in the developed continents, such as North America and Europe, and in 15 percent of renal transplant recipients in developing countries with a high prevalence of tuberculosis, such as India or Pakistan.* Tuberculosis may develop in renal transplant recipients as a result of primary and reactivation infection in almost any site, and transmission from the renal allograft and reactivation in the native kidney have occurred.[127,160,161,202] *M. tuberculosis* may cause various diseases, including pulmonary infiltrates, cavitary lesions, adenopathy, cutaneous lesions, bone and joint disease, liver or spleen granulomas, and meningitis. Fever frequently is noted, and miliary or disseminated disease may occur, especially in young children.

Because the TST is negative in most renal transplant recipients with active tuberculosis, the diagnosis is determined best by IGR assays, detection of acid-fast bacilli in smears from tissue or sputum, and isolation of *M. tuberculosis* in cultures of gastric aspirates, sputum, tracheal secretions, spinal fluid, or tissue.[138,185] The presence of granulomas in tissue also suggests the diagnosis of tuberculosis.

Treatment of tuberculosis in a renal transplant recipient usually includes isoniazid, rifampin, and pyrazinamide for 1 year, although shorter courses may be acceptable in some patients.[135,185] Other antituberculous drugs may be added to or substituted for this standard regimen, depending on the disease process, the susceptibility pattern of the organism, and potential drug interactions. Because many antituberculosis drugs are excreted by the kidney, doses may need to be adjusted in a renal transplant recipient. Because rifampin may interact with cyclosporine, levels of cyclosporine should be monitored closely to avoid rejection of the allograft.[174] If a history of tuberculosis exposure is elicited during the pretransplant evaluation, the transplant candidate should be evaluated for tuberculosis, including having a TST, IGR assay on blood, and chest radiograph.[160,161,195] All close contacts also should be investigated for evidence of having tuberculosis. Treatment is recommended if disease is discovered, and prophylaxis with isoniazid is indicated for most patients who have a recently positive result of a purified protein derivative (PPD) test on pretransplant evaluation.[135,185,186,210,256] A transplant recipient who receives an allograft from a donor with a history of tuberculosis or a positive TST or IGR assay also may be a candidate for prophylaxis with isoniazid after a transplant procedure.[135,185,186]

Atypical mycobacteria are ubiquitous nontuberculous mycobacteria that can infect and produce disease in renal transplant recipients. They can cause disease during the middle posttransplant period and so are included here. Their effects usually do not become evident, however, until many years after the patient has undergone transplantation, during the late posttransplant period.[48,161,187] Atypical mycobacteria that have been documented to cause disease in solid-organ transplant recipients include *M. kansasii*, *M. avium-intracellulare*, *M. fortuitum*, *M. xenopi*, *M. haemophilum*, *M. marinum*, *M. chelonae*, *M. abscessus*, *M. gastri*, *M. scrofulaceum*, and *M. thermoresistibile*.[117,185,186]

A high index of suspicion is necessary to detect these elusive pathogens. They should be considered as the cause of disease in patients with persistent cutaneous ulcers, abscesses, adenopathy, pulmonary nodules, chronic wound infections, or bone and joint disease after negative routine bacterial cultures have been obtained and the patient has failed to respond to standard antimicrobial therapy.[206] Disseminated, multisystemic disease also can occur. Environmental sources of atypical mycobacteria include contaminated dialysis equipment, soil, and contaminated water in aquariums and pools. The diagnosis is established by isolation of nontuberculous mycobacteria in fluid or tissue. Granulomas are not observed consistently in tissue, and acid-fast stains may be negative.[206] Atypical nontuberculous mycobacteria are difficult to treat, and treatment must be individualized to each patient. Strategies include reduction of immunosuppression and surgical débridement of localized disease. Antimicrobial therapy based on in vitro susceptibility testing of the isolate also should be administered, often for a prolonged period.

Nocardia

Nocardia asteroides is the most common *Nocardia* spp. causing illness in renal transplant recipients; however, other, more unusual *Nocardia* spp., including *N. transvalensis*, *N. brasiliensis*, *N. nova*, *N. otitidiscaviarum*, and *N. farcinica*, also have been shown to cause disease in solid-organ transplant recipients.[185,186,251] The most common manifestations of nocardial disease in transplant recipients are fever, cough, and pulmonary infiltrates.[251] Pleural effusion, pulmonary nodules, and cavitary lesions also may occur. Cutaneous infection, adenitis, arthritis, meningitis with brain abscesses, and infection of the renal allograft also may occur. *Nocardia* spp. can be seen on Gram and modified acid-fast stains of sputum, bronchoalveolar lavage fluid, abscess fluid, and tissue. They can be isolated on routine media but may take longer than conventional bacteria to grow. Prolonged treatment with sulfonamides, alone or in combination with trimethoprim, is recommended. Amikacin and other antimicrobial agents may be added in selected patients with severe disease, provided that renal function is monitored closely.[206] Trimethoprim-sulfamethoxazole prophylaxis for UTI and *P. jiroveci* also may be effective in preventing disease caused by *Nocardia*.

Fungal Diseases

Fungal infections occur infrequently in renal transplant recipients relative to other solid-organ transplant recipients.[12,185,186,206] This lower rate of infection probably is related to technical procedures performed at the time of transplantation and the lower level of immunosuppression required to maintain most renal allografts.[206] When they do occur, however, fungal infections often are serious and life threatening.[95,99,109] Fungal disease in a renal transplant recipient usually is manifested in one of two ways:

*References 117, 185, 195, 202, 209, 210.

(1) pulmonary or disseminated disease caused by one of the environmental mycoses, such as *H. capsulatum* or *C. immitis*, or (2) opportunistic infection with fungi that rarely cause disease in a normal host, such as *Candida* spp., *P. jiroveci*, *Aspergillus* spp., *Cryptococcus neoformans*, *Nocardia* spp., and others.[95,219]

Travel to endemic areas increases a transplant recipient's risk for development of histoplasmosis and coccidioidomycosis and may be identified during the pretransplant evaluation. Factors that increase a transplant recipient's risk for acquisition of opportunistic fungal disease include underlying conditions such as diabetes mellitus, repeated episodes of rejection, long-term administration of corticosteroids, prolonged use of antibiotics, and CMV infection. Similar to tuberculosis, invasive fungal disease can be a result of primary infection or reactivation infection with secondary dissemination.[206] *P. jiroveci*, currently classified as a fungus, may cause pneumonia in 10 percent of solid-organ transplant recipients, most often during the first 6 months after a transplant procedure.[9,185,186] It seems to occur more commonly in children than in adults and usually causes fever, dyspnea, tachypnea, hypoxemia, and a nonproductive cough.[64,185] Interstitial pulmonary infiltrates are typical findings, but almost any radiographic picture can be observed, and pneumothorax is common in severe disease. The diagnosis can be suspected clinically but is documented best by organisms being shown in lung biopsy specimens; bronchoalveolar lavage may provide the diagnosis in some patients.

Treatment with high-dose oral or intravenous trimethoprim-sulfamethoxazole for 14 to 21 days is used most often. Intravenous pentamidine may be administered to selected patients, but renal function should be monitored carefully.[206] Corticosteroids may be helpful in treating severe disease if given early in the course. Low-dose oral trimethoprim-sulfamethoxazole provides effective prophylaxis against *P. jiroveci* pneumonia and UTIs and usually is administered to renal transplant recipients for at least 6 months post transplant.[77] Transplant recipients experiencing repeated episodes of rejection, allograft dysfunction, or CMV disease may require a longer period of prophylaxis.[185,186] Aerosolized pentamidine is an alternative prophylaxis strategy for some patients.[206]

Candida spp., especially *C. albicans*, are the opportunistic fungi most frequently isolated in renal transplant recipients.[185,186] Other *Candida* spp. isolated include *C. krusei*, *C. glabrata*, and *C. tropicalis*. Most fungal infections caused by *Candida* spp. occur during the first 2 months after transplant surgery, usually at the site of indwelling intravascular and urinary catheters.[206] Esophagitis, abscesses, and arthritis also can develop, and endocarditis with metastatic foci can occur if the fungemia persists. Other opportunistic fungi such as *Aspergillus* most often cause sinusitis and pulmonary disease, and, because of its angioinvasive nature, *Aspergillus* often disseminates and causes lesions in the liver, spleen, and brain.[185,186,219,220]

A thorough search for metastatic foci always should be undertaken when a primary focus of invasive fungal disease is documented. *C. neoformans* usually causes cutaneous lesions or abscesses and pneumonia with pleural effusion, but meningitis, arthritis, and pyelonephritis also can occur.[185,186,214] Exposure to soil or bird droppings provides an epidemiologic clue to the diagnosis. In addition, the Zygomycetes, including *Rhizopus*, *Mucor*, *Rhizomucor*, and *Absidia* spp., can cause disease in solid-organ transplant recipients.[219,220] They most often cause cutaneous, rhinocerebral, or pulmonary disease or brain abscesses in renal transplant patients. Cutaneous and soft tissue infections, wound infections, and gastrointestinal disease with perforation also have been described. The Zygomycetes, similar to *Aspergillus*, are angioinvasive and disseminate via the bloodstream to cause disease, which often is severe. A variety of unusual fungi, such as *Paecilomyces*, *Fusarium*, and *Bipolaris*, have been shown to cause cutaneous infection, usually at the site of indwelling catheters, and *Hansenula anomala* reportedly has caused UTI in a renal transplant recipient.[86]

The endemic dimorphic fungi include *H. capsulatum*, *C. immitis*, *B. dermatitidis*, and *Paracoccidioides brasiliensis*. Infection with these organisms can occur at any time after the patient has undergone transplantation but usually occurs during the intermediate posttransplant period.[233] These organisms usually are noted in renal transplant recipients who reside in endemic areas. Histoplasmosis is endemic in the central part of the United States and many foreign countries, and nosocomial outbreaks have occurred during hospital construction projects. Fever, chills, and cough are the usual initial signs. Skin lesions, hepatosplenomegaly, and meningitis also can occur. Pancytopenia often is present as well, and the organism frequently is found in the bone marrow of patients with disseminated disease. Coccidioidomycosis is endemic in the southwestern portion of the United States and northern Mexico. It usually is manifested as fever, cough, and pulmonary infiltrates, but extrapulmonary dissemination frequently occurs. Blastomycosis is endemic in the southern United States, along the Mississippi and Ohio River valleys, and in the Great Lakes area. It is a rare development after renal transplantation, but most often causes lung and skin lesions. Paracoccidioidomycosis rarely has been reported in renal transplant recipients.[228]

The diagnosis of invasive fungal disease is established best by isolating the fungus from sputum or tracheal aspirate, bone marrow, tissue, or fluid. Serum tests and bronchoalveolar lavage for galactomannan and 1-3-β-D-glucan levels support the diagnosis of invasive fungal disease, and DNA PCR tests on serum and bronchoalveolar lavage fluid also may now be performed to detect *Candida* spp. and other fungi.[12]

C. neoformans also may be isolated from urine. Fungal specific serology and tests for cryptococcal antigen may support the diagnosis of cryptococcal infection.[228]

Fungal identification and susceptibility testing now can be performed in clinical and reference laboratories and should be used to guide therapy whenever possible. Amphotericin B usually is used to treat most invasive fungal disease in transplant recipients, and the deoxycholate, lipid complex, or liposomal forms can be used, provided that renal function is monitored closely.[136] Flucytosine may have additive or synergistic effects against many yeasts and fungi. The azole antifungal agents are not nephrotoxic and are used in renal transplant recipients whenever possible. Many *Candida* spp. are susceptible to fluconazole, although resistance is emerging in all *Candida* spp. and is present in a high percentage of *C. krusei* and *C. glabrata*. Itraconazole and

voriconazole may be effective against other fungi, such as *Aspergillus*.[12] Voriconazole is the treatment of choice for most *Aspergillus* infections. Itraconazole should be used with caution because it has variable oral absorption and may interact with cyclosporine.[233] Caspofungin, an echinocandin, also has activity against most *Candida* spp. and a variety of opportunistic fungi, including some species of *Aspergillus*. The triazole posaconazole and the echinocandin micafungin have also been used successfully in pediatric renal transplant recipients with invasive fungal disease.

Surgical resection or drainage of abscesses, avascular cavities, or effusions may be required to treat some forms of invasive fungal disease of the lungs, liver, or spleen. Carefully monitored reduction in immunosuppression also may help the host recover from invasive fungal disease.

Parasitic Infections

The parasites most commonly encountered in renal transplant recipients during the intermediate posttransplant period are *T. gondii*, *S. stercoralis*, and *Trypanosoma cruzi*.[73,185] These infections occur most often in adults. Children also may be infected with routine parasites such as *Enterobius vermicularis*, *Ascaris*, *Giardia*, and others before a transplant operation. Other parasitic infections that may be found in renal transplant recipients include leishmaniasis, schistosomiasis, and malaria. Renal transplant recipients seem to be at much lower risk for acquisition of parasitic diseases than are other solid-organ transplant recipients.

Infection with *T. gondii* usually occurs as a result of reactivation of latent disease in the donor allograft or recipient.[144] It is encountered most frequently in heart transplant recipients, but any solid-organ recipient, including renal transplant patients, may be affected. Clinical manifestations of infection with *T. gondii* include focal meningoencephalitis, brain abscesses, pneumonia, myocarditis, pericarditis, hepatitis, and retinochoroiditis.[155,225,233,240] The diagnosis may be made by demonstration of the organism in tissue by histopathology, detection of DNA by PCR in body fluids or tissue, or serologically by detection of high titers of IgG and specific IgM antibody to *T. gondii*. Treatment with pyrimethamine, sulfadiazine, and folinic acid usually is recommended; however, some patients also may respond to clindamycin. Routine prophylaxis with trimethoprim-sulfamethoxazole for UTI and *P. jiroveci* infection may help prevent disease with *T. gondii*.

S. stercoralis is an important pathogen in adult transplant recipients, but it is rarely, if ever, a significant problem in pediatric patients. Because *S. stercoralis* can be maintained in the human intestinal tract for decades, it can disseminate and cause serious disease in transplant recipients who were infected before the procedure. A complete blood cell count for eosinophilia should be obtained, and stool and other specimens should be examined for rhabditiform larvae if the pretransplant evaluation reveals travel to endemic areas. Thiabendazole should be given before transplantation is performed if *S. stercoralis* infection has been documented or is suspected. *T. cruzi*, the cause of Chagas disease, rarely has been transmitted by renal transplantation.[73,133]

Infections Occurring During the Late Posttransplant Period

Infections occurring 6 months or more after the patient has undergone renal transplantation usually are less severe than infections experienced in the earlier periods, especially if the level of immunosuppressive therapy is low and the allograft is functioning well.[205] Constant vigilance for health care–associated and community-acquired viral and bacterial diseases and unusual infections should continue, however.

Chronic rejection or repeated episodes of acute rejection complicated by allograft dysfunction predispose the patient to development of more serious opportunistic infections, similar to infections encountered during the first 6 months after a transplant. UTIs that develop during this period, in contrast to UTIs in the early posttransplant period, usually are benign, especially if the patient is afebrile, and may be treated with conventional antimicrobial therapy in most instances, if they do not seem to threaten the function of the allograft or the patient's survival. Patients also may experience community-acquired infections with respiratory viruses, such as influenza virus and respiratory syncytial virus, and with bacteria, especially *Streptococcus pneumoniae* (pneumococcus) or *S. aureus*. These common community-acquired bacterial pathogens may be resistant to usual β-lactam antibiotics.[226,238] In addition, patients vaccinated with 7-valent or 23-valent pneumococcal vaccines still may acquire invasive pneumococcal disease with emerging, nonvaccine serotypes, such as 19A and 3A. These serotypes often are also multidrug-resistant. Opportunistic viral infections encountered during this period are zoster or, rarely, CMV retinitis.[164] The risk for developing PTLD and BKAN also persists during this late posttransplant period.

Renal transplant recipients may be chronically infected with HBV or HCV before a transplant is performed. Increased risk for mortality from fulminant hepatitis with hepatic failure may occur during the early pretransplant period, and chronic liver disease, cirrhosis, and liver failure may be seen 10 years or more after renal transplantation has been performed in hepatitis B surface antigen (HBsAg)–positive recipients.[255] All transplant recipients who are not immune to HBV should receive HBV vaccine before transplantation.[247] Most experts agree that renal allografts from HBsAg-positive donors should not be used, but the decision to perform renal transplantation in recipients who are HBsAg-positive is controversial and must be made on an individualized basis.

Renal transplant recipients who are infected with HCV before the transplant usually do well during the early posttransplant period, but long-term survival is poorer than in recipients who are not infected with HCV. Not only can chronic liver disease develop, but also membranoproliferative glomerulonephritis has been reported in renal transplant recipients infected with HCV.[32] Despite these risks, however, most experts do not

consider infection with HCV a contraindication for renal transplantation in patients with ESRD.[190] Hepatitis G virus also has been detected in the serum of renal transplant recipients, and at least one association with membranous glomerulonephritis has been reported.[16,17] The role of HGV in clinical disease in renal transplant recipients is not established, however.

HIV may be transmitted by kidney transplantation despite routine screening of donors of blood and organs.[130,200] A transplant recipient also may become infected with HIV after undergoing transplantation.[185] Shortly after a patient has undergone transplantation, HIV infection may cause fever and a mononucleosis-like syndrome. Complications of acquired immunodeficiency syndrome may develop during the late transplant period. HIV-infected patients with ESRD are no longer excluded from receiving renal transplantation because recent studies have shown successful outcomes.[97,100,165,185]

CHAPTER 74

Infections Related to Prosthetic or Artificial Devices

Ram Yogev • Tina Q. Tan

The development of biomaterials used in the manufacturing of temporary or permanent implantable prosthetic devices has been one of the greatest advances in modern medicine.[90,114,115] These devices have become an integral and important part of the current practice of medicine and have improved considerably the lives and health of countless patients. In the United States, the number and types of permanent prosthetic devices implanted to replace diseased or damaged body parts has increased substantially during the last several decades. An estimated

TABLE 74-1 **Partial List of Implantable Devices Prone to Infection**

Central nervous system shunts
Intracranial pressure monitors
Intrathecal pump infusion
Orthopedic prostheses (artificial hip, knee, and other joints; screws, pins, plates, and rods)
Intracardiac pacemakers and defibrillator
Left ventricular assist devices
Extracorporeal membrane oxygenation circuits
Ocular prostheses (artificial globes, intraocular lenses, ocular explants)
Cochlear implant devices
Tissue expander devices

3 million or more people in the United States currently have some type of long-term biomedical implant.[105,402,478] Table 74-1 lists implantable prosthetic devices discussed in this chapter.

One of the major medical complications associated with the use of implantable prosthetic devices is infection, which may result in serious tissue destruction and dysfunction of the prosthetic device or in local and systemic consequences that may be life-threatening. In most cases, these infections are very difficult to cure with antimicrobial agents alone, and removal of the device usually is required for resolution of the infection.

INTERACTION OF THE HOST WITH A PROSTHETIC DEVICE

The prosthetic devices currently in use are composed of a variety of biomaterials, including cobalt-chromium-molybdenum alloy, titanium alloy, and complex polymers such as polytetrafluoroethylene, silicone, and polyethylene, which in general are chosen for their inert, nonreactive, and nontoxic qualities. The interplay of both implant and host factors determines the risk for acquiring and the severity of infection. The human body has numerous well-developed defense mechanisms to protect it against possible invasion by various microorganisms. Such mechanisms include cellular and humoral immune systems, anatomic barriers, and an elaborate network of cells that phagocytize and destroy invading organisms. The presence of a foreign body may compromise one or more of these defenses and elicit a complex acute or chronic inflammatory response (or both) from the host. Many of these devices breach cutaneous and mucosal barriers, thereby creating a direct route by which bacteria and fungi may invade. In addition, implanted devices may alter the local immunity of the host directly or indirectly.[114,402,478,504]

Shortly after being implanted, hydrophobic polymeric materials such as polyethylene, Dacron, polydimethylsiloxane, and polyether urethanes become coated with a layer of host proteins such as plasma and interstitial fluid proteins (i.e., fibronectin, albumin, laminin, collagen, immunoglobulin G, fibrinogen) that bind to and are absorbed readily into the surface of the implant.[32,363,479] This protein layer (especially fibrinogen) has a major influence on the body's response to and the biocompatibility of the implant. The presence of fibrinogen attracts a large number of phagocytic cells (i.e., neutrophils, monocytes, and macrophages) to the implant; these cells interact with the implant surface and initiate an acute inflammatory response.[114,478] Some of these host proteins also serve as a receptor for various colonizing microorganisms. Collagen, laminin, and fibrinogen have been reported to play a role in adherence of bacteria,[509] and fibronectin has been found to be the major receptor for gram-positive cocci, especially *Staphylococcus aureus*.[392,487]

Chronic inflammatory responses, also known as *foreign body reactions*, are seen around many types of biomaterial implants and arise from interactions among the protein-coated surfaces of the implant and host tissues and adhering phagocytic cells such as macrophages and foreign body giant cells. These interactions may result in degradation and damage to the implant from the continuous generation of toxic catabolites and release of inflammatory mediators such as hydrolases, activated complement components, tumor necrosis factor (TNF), interleukins, prostaglandins, coagulation factors, and plasminogen activator by the phagocytic cells.[474,478,504]

INTERACTION OF MICROORGANISMS WITH A PROSTHETIC DEVICE

Once a prosthetic device is implanted, the surface of the device provides a potential area for adherence and multiplication of bacteria. Adherence is a complex process that involves electrostatic attachment of the bacteria to the surface of the implant, bacterial mechanisms that function specifically in attachment, and host-derived substances that coat the prosthetic device and serve as receptors for various bacteria. Bacteria arrive at the surface of the implant by many different routes; they may be inoculated at the time of implantation, the patient may have episodes of transient bacteremia, the device may be exposed by local trauma or infection, or the device may be implanted within an area in which the organism is part of the normal flora.[105,114]

Adherence of bacteria to the surface of an implant is influenced by numerous different factors, including the material used to make the device, the source of the device material (adherence is greater with synthetic material than with biomaterial), the surface of the device (i.e., irregular more than regular, textured more than smooth, hydrophobic more than hydrophilic), and the shape of the device.[105] Cell surface molecules or structures known as *adhesins* also play a role in adherence by attaching or binding an organism to specific receptors on implant surfaces; different bacteria use different adhesins to attach to and colonize medical implants. For example, *Staphylococcus epidermidis* uses proteinaceous autolysin and capsular polysaccharide intercellular adhesin for initial adherence to the implant surface and for adherence of bacteria to each other. These bacteria also produce a biofilm that increases cell-to-cell association and allows accumulation of bacteria.[409] *Streptococcus pyogenes* uses lipoteichoic acid as its adhesin, whereas *S. aureus* uses

both lipoteichoic acid and host-tissue ligands (e.g., fibronectin, fibrinogen, and collagen) for adherence. Binding of *S. aureus* to host-tissue ligands is mediated by genetically defined microbial surface proteins known as *microbial surface components recognizing adhesive matrix molecules* (MSCRAMM).[106] *Escherichia coli* and other bacteria use fimbriae as an adhesin to mediate binding to receptors on the surfaces of target cells.

Bacteria also can protect themselves from host defenses by synthesizing and excreting numerous complex polysaccharides, known as *glycocalyces*, that function either as part of the bacterial capsule or as the slime layer. This slime layer is known to play a major role in keeping an organism attached to an implant surface by coalescing with the polysaccharides of other bacteria and with host products to produce a thick, adherent, and somewhat impenetrable biofilm.[505] The biofilm functions by trapping nutrients and protecting the organism from phagocytosis, antimicrobial agents, and competing microflora. It also plays a role in inhibiting the response to chemotactic stimuli, increases both *N*-formyl-methionyl-leucyl-phenylalanine (FMLP)-induced superoxide generation and release of specific granules, and impairs natural killer cell function while also altering the composition of T-lymphocyte cell subpopulations.[170,172,227,505] Therefore, the biofilm aids bacteria in evading host cellular and humoral defense mechanisms and thereby allows the organism to colonize and infect an implanted device effectively.

Substantial progress has been made in our understanding of the pathogenesis, prevention, and treatment of foreign body infections; this increased knowledge has resulted in a dramatic decrease in the morbidity associated with these infections, as well as subsequent improvement in the patient's quality of life. The following sections discuss specific device-related infections and the suggested treatment and management of these infections.

TISSUE EXPANDERS

The use of soft tissue expansion in reconstructive surgery was reported in the literature first in 1957, and since that time it has been used widely for the correction of multiple problems in plastic and reconstructive surgery in the adult and pediatric populations.[19,27] These expanders consist of an alloplastic prosthesis with a filling port that is implanted into a subcutaneous pocket. The expander is filled with saline through the filling port at various intervals to create adequate expansion of the skin. Subsequent improvements of this technique led to the development of osmotic tissue expanders. The Osmed osmotic tissue expander is made of an osmotically active hydrogel (vinyl pyrrolidone and methyl methacrylate) in a silicone construct. When implanted, water is drawn from the surrounding tissues into the device, which can spontaneously expand up to 10 times its original volume. In children, tissue expansion is used most commonly to provide coverage for skin defects caused by burns, trauma, hemangiomas, and other congenital deformities.*

*References 57, 87, 307, 351, 476, 534.

The most common complication of tissue expansion is infection of the subcutaneous expander pocket, usually with skin organisms introduced during insertion of the expander. Cellulitis of the overlying skin and hematogenous or lymphatic seeding of the expander pocket are seen as well but occur much less frequently.* In several pediatric case series, the infection rate ranged from 3.4 to 11 percent.[1,159,307] *S. aureus*, *S. epidermidis*, and group A streptococci are the microorganisms recovered most commonly from these infections.[159,215,302,307] Less commonly, nontypable *Haemophilus influenzae*,[307] *Pseudomonas aeruginosa*, *E. coli*, and *Actinomyces* spp.[327] have been isolated from infections of expander pockets.[302]

In cases of infection of subcutaneous pockets, treatment consists of removal of the tissue expander, débridement and drainage of the subcutaneous pocket, and administration of intravenous antibiotic therapy tailored to the organism isolated. For cellulitis of the overlying skin of an expander pocket, treatment with intravenous antibiotics but without removal of the tissue expander has been shown to be successful.[19]

The most common empirical antimicrobial therapeutic regimen consists of a first-generation cephalosporin or an extended-spectrum, penicillinase-resistant penicillin. For all of the infections of prosthetic devices discussed in the chapter, empirical antistaphylococcal coverage should include agents effective against community strains of methicillin-resistant *S. aureus* (MRSA) if warranted by their frequency in the area.

Therapy is tailored once the organism has been identified and its antibiotic susceptibility has been determined.

COCHLEAR IMPLANTS

During the last several decades, cochlear implantation has emerged as one of the best methods of providing auditory rehabilitation for the profoundly deaf (congenital or acquired). The goal of this surgery in young children is to provide hearing that is adequate to facilitate the development of receptive and expressive language. The surgical technique involves the creation of a C-shaped flap in the postauricular and parietal-occipital scalp skin areas, elevation of the flap, implantation of a multichannel prosthesis, and insertion of an electrode array into the cochlea through openings drilled into the temporal bone.[95,98,295]

The most common infectious complications associated with these implants are cellulitis of the overlying skin flap, meningitis, otitis media, and delayed cochlear implant infections leading to extrusion of the implant.† Rates of infection range from 0.3 to 0.5 percent for meningitis, 2 to 12 percent for cellulitis of the skin flap and delayed cochlear implant infections, and to 36 percent for otitis media. The reported cases of meningitis have occurred in association with leakage of cerebrospinal fluid (CSF) in persons with a malformed cochlea who

*References 19, 149, 159, 215, 300, 307, 343.
†References 45, 96, 97, 102, 108, 162, 183, 189, 198, 199, 209, 218, 220, 288, 323, 344, 361, 527.

undergo cochlear implantation, as a consequence of intracranial spread of a developing middle ear infection along the electrode pathway, or via pneumococcal bacteremia with hematogenous seeding of the cochlea—for example, at a site of tissue necrosis related to the electrode or positioner with contiguous spread to the CSF and meninges. In June 2002, the U.S. Food and Drug Administration received numerous reports of bacterial meningitis in children with cochlear implants who were younger than 6 years old when they received the implants. The most common causative organism identified was *Streptococcus pneumoniae*, followed by nontypable and type b *H. influenzae*. Other less common organisms that have been reported include *S. pyogenes*, *Acinetobacter baumannii*, *Escherichia coli*, and *Enterococcus* spp.[401] The incidence of pneumococcal meningitis in this group of patients was calculated to be 138.2 cases/100,000 person-years—more than 30 times the incidence in the same-aged cohort in the general population. This increased incidence of meningitis was found to be associated strongly with the use of a cochlear implant with a positioner (a wedge-shaped insert that facilitates transmission of the electrical signal by pushing the electrode against the medial wall of the cochlea) in conjunction with the presence of radiographic evidence of a malformation of the inner ear and leakage of CSF. Cochlear implants with a positioner were voluntarily recalled in the United States in July 2002, although removal of existing implants containing a positioner was not recommended; use of appropriate vaccination against *S. pneumoniae* and type b *H. influenzae* was strongly recommended.[26,48,168,401] On February 24, 2010, a 13-valent pneumococcal conjugate vaccine (PCV13) was licensed by the U.S. Food and Drug Administration. This vaccine contains polysaccharides of the seven serotypes in PCV7 and polysaccharides from 6 additional serotypes. This vaccine replaces PCV7 for all scheduled doses of PCV7 in infants. A supplemental dose of PCV13 is recommended for children 14 months through 18 years of age with a cochlear implant.[2] Children with cochlear implants may have a higher risk for middle ear infections because of several factors, including the naturally high incidence of acute otitis media in this population, the presence of a foreign body in the area of the infection, and the potential for spread of the infection into the cochlea along the electrode pathway. In a study of 50 children who received cochlear implants between 1991 and 1995, researchers found that children prone to the development of otitis media before undergoing implantation were at higher risk for developing postimplantation acute otitis media but responded well to routine oral antimicrobial therapy. The overall prevalence and the severity of acute otitis media were not found to be increased in children with cochlear implants.[292]

In cases of cellulitis of the skin flap, intravenous antimicrobial therapy should include empirical broad-spectrum antimicrobial agents effective against community strains of MRSA, methicillin-susceptible strains of *S. aureus*, and group A streptococci. Empirical antimicrobial therapy for meningitis usually consists of vancomycin and a third-generation cephalosporin that is tailored to the organism isolated. An exception is for children with the onset of meningitis during the first 2 weeks after cochlear implantation; in these instances, causal bacteria may include a broader range of pathogens, including gram-negative bacilli and gram-positive bacteria. Selection of a combination of antimicrobial agents that provides broader-spectrum coverage against gram-negative bacilli should be chosen. For delayed development of cochlear implant infections, therapy consists of removal of the implant and administration of intravenous antibiotics.[402,406]

OCULAR PROSTHESES

The ocular prosthetic devices include artificial globes used primarily for cosmetic purposes, orbital implants, ocular explants, intraocular lenses, and contact lenses.

Orbital Implants

Orbital implants are made of hydroxyapatite or porous polyethylene and frequently are used in orbital reconstruction after enucleation or evisceration surgery. Infection of these implants is a rare event, with only a handful of cases reported in the literature.* Patients most commonly report anophthalmic socket pain or discomfort, pain with eye movement, and excessive conjunctival edema and irritation while wearing an artificial globe.[229] Papillary conjunctivitis of the socket with exudate and sometimes dehiscence of the overlying conjunctiva also may be seen.[160,337] Infection may develop months to years after placement of the implant, and severity ranges from cellulitis to the development of an abscess around the implant itself, with implant extrusion. In a retrospective clinical case series of 103 patients who underwent hydroxyapatite implant insertion at one institution, patients who had a freestanding polycarbonate peg placed to enhance the motility of their ocular prostheses had a significantly higher rate of infection than those patients with nonpegged hydroxyapatite implants, at 42.9 versus 19.5 percent.[135]

Radiographic studies that can aid in the detection of these types of infection include technetium 99m–labeled leukocyte scintigraphy, which is most useful in detecting early low-grade graft infection,[228] and computed tomography (CT) and magnetic resonance imaging (MRI), which are useful later in the course of the infection to detect the presence of abscesses and structural tissue changes. Gram-positive cocci, primarily *S. aureus*, and coagulase-negative staphylococci are the organisms associated most commonly with these infections; however, *H. influenzae*, *S. pneumoniae*, α-hemolytic streptococci, *Capnocytophaga*, *Pseudomonas*, and *Aspergillus fumigatus* have been cultured as well.† To cure the infection effectively, treatment involves both removal of the implant and institution of topical and parenteral antibiotic therapy directed against the organism isolated. Empirical therapy directed against gram-positive organisms may be started initially

*References 5, 134, 161, 208, 231, 238, 545.
†References 88, 401, 408, 436, 464, 538, 546.

until the results of culture and sensitivity testing are available. This should include antimicrobial agents effective against community strains of MRSA. In addition, other common empirical regimens include a first-generation or second-generation cephalosporin or an extended-spectrum, penicillinase-resistant penicillin.

Intraocular Lenses

Insertion of polymethyl methacrylate (PMMA) intraocular lenses at the time of removal of a cataract is the standard surgical therapy for this disorder. Even though the rate of postoperative infection of intraoperative lenses is low (0.10% to 0.30%), the infection usually is serious and results in endophthalmitis and permanent loss of vision.[231,258] The predisposing factor for infection is bacterial adhesion to intraocular lenses during insertion. After adhesion is accomplished, the bacteria replicate, congregate, and form multiple layers of microcolonies that represent a biofilm in which the bacteria are embedded in a layer of slime. The major pathogens associated with this infection are *S. aureus* and *S. epidermidis*, which account for 90 percent of all isolates, although α-hemolytic *Streptococcus* spp., gram-negative bacilli, *Pseudomonas*, fungi, *Chlamydia trachomatis*, *Nocardia* spp., and rapidly growing mycobacteria are isolated on occasion.* Intraocular lens–associated endophthalmitis is a serious infection that is difficult to diagnose and treat.[34,394,477,492,530] In a few cases, use of topical and systemic antibiotics alone has been successful in eradicating the infection, but in most cases surgical débridement and systemic antibiotics are required for cure. Empirical therapy for these infections consists of an extended-spectrum, penicillinase-resistant penicillin, a second-generation cephalosporin, or, in some instances, clindamycin or vancomycin. In cases of fungal endophthalmitis, treatment with the later-generation azoles alone and in combination with an echinocandin has been shown to have clinical success.[121] In rapidly growing mycobacterial endophthalmitis combinations of topical and intravenous antibiotics to which the organism is susceptible have been used for treatment.[311]

Contact Lenses

Primarily three different types of contact lenses are available. Hard lenses are made of PMMA, a substance that is impermeable to water and gas. This type of lens is designed to be worn only during waking hours because it limits oxygen flow to the cornea to that present in tears. Gas-permeable hard lenses are composed of silicone, cellulose acetate butyrate, or PMMA-silicone copolymers; they allow gas but not fluid to pass through the lens. Hydrophilic or soft lenses are made of a cross-linked hydrogel polymer or copolymer and consist of 38 to 85 percent water by weight; these lenses are permeable to both gas and water and allow the user to wear them continuously. However, for all these types of lenses, infection may result in damage to the corneal epithelium.

The two main infections that occur in association with contact lenses are conjunctivitis and keratitis.[77] The causative bacteria seen most commonly with these infections are *S. aureus*, streptococci, *Pseudomonas* spp. (found in improperly stored cleansing solutions), and fungi (including *Candida* spp., *Alternaria*, *Paecilomyces*, *Fusarium*, *Curvularia*, and other filamentous fungi, and *Acremonium*). Improper cleaning of soft or hydrophilic lenses may cause them to become a source of infection when bacteria penetrate the lens matrix. Risk factors for fungal keratitis include use of contaminated contact lens solution,[8,79,499,549] trauma, contact lens wear, ocular surface disease, systemic diseases affecting the immune system, diabetes, use of systemic steroids, and recent chemotherapy. Fungal keratitis frequently is a severe disease in which diagnosis may be difficult, response to medical therapy is generally slow, and the clinical outcome may be poor. Corneal perforation is 5 to 6 times more likely with fungal keratitis than in bacterial keratitis.[542] In a retrospective multicenter case series of 733 cases of fungal keratitis that looked at the epidemiology and microbiologic characteristics of fungal keratitis at tertiary eye care centers in the United States, it was found that filamentous fungi were more commonly found as the cause of keratitis among refractive contact lens wearers while yeasts, especially *Candida* spp., were the most common causative organisms in patients with ocular surface disease and ocular trauma.[240,548] Treatment of keratitis usually consists of removal of the lens and application of topical antibiotics or antifungals. The most commonly used topical antifungal regimen is a combination of natamycin 5 percent and amphotericin B 0.15 percent. Twenty-five percent of patients also may require systemic antifungal therapy in addition to the topical therapy. In fungal keratitis, 16 to 26 percent of patients require surgical intervention with therapeutic keratoplasty in addition to medical therapy.[219,240] To prevent the development of infections associated with contact lenses, users should adhere strictly to the manufacturer's suggested guidelines for wearing and cleaning the lenses.

A rare and often devastating infection associated with the use of contact lenses is infection with the fresh-water protozoan *Acanthamoeba*.[93,195,337,467] This organism contaminates the lens when sterility of the cleansing solutions is not maintained; it has been associated with users who prepare their own solutions and use of contaminated contact lens disinfection solution.[107,508,551] *Acanthamoeba* is very difficult to eradicate because it is not susceptible to standard antiparasitic agents, and it produces a chronic keratitis that can be complicated by corneal perforation and loss of the eye. Corneal transplantation may be necessary in many cases to restore vision.[195,467] In a study by Kaiserman and colleagues to assess the prognostic factors influencing visual prognosis and length of treatment after acanthamoeba keratitis, infection acquired by swimming or related to contact lenses, having neuritis and pseudodendrites, the absence of an epithelial defect, having been treated with chlorhexidine, and not having received steroids were factors that were associated with better final best spectacle-corrected visual acuity (BCVA); having an epithelial defect on presentation and having been treated with topical steroid were associated with worse BCVA.[230]

*References 11, 121, 258, 311, 371, 372, 435, 547.

LEFT VENTRICULAR ASSIST DEVICES

The development plus use of mechanical circulatory assist devices has grown very rapidly in the last several decades, especially with the shortage of available donor hearts. Such devices have improved considerably the hemodynamic status and quality of life of patients with heart failure who are awaiting cardiac transplantation. Figure 74-1 shows a left ventricular assist device (LVAD), a pneumatically driven pump located outside the heart that draws blood from an inflow cannula in the left ventricular apex and ejects the blood through an outlet into the ascending aorta. Within the pump are several sections of Dacron graft material and two trileaflet porcine valves in the inflow and outflow positions to ensure that blood flow is unidirectional. The pump is encased in titanium and implanted via an extended median sternotomy into the left rectus sheath. A percutaneous driveline connects to an exterior power pack for venting or for pneumatic actuation and exits the body after passing through a subcutaneous tunnel, in the left lower quadrant. The interior surface of the pump is textured to prevent the formation of thrombi and encourage the deposition of a biologic pseudointimal lining. Most LVADs are surgically implanted through a median sternotomy, with pump placement primarily in the intra-abdominal or preperitoneal space. Ventricular assist device designs primarily fall into two major categories: pulsatile and continuous flow devices. Pulsatile devices are first-generation devices that were designed to mimic nature by providing pulsatile circulation, but have many moving parts, including a diaphragm to hold and eject blood, valves to maintain directionality, and an air vent and conduit for cooling of the working parts. These requirements have limited the durability and size of these devices. Because of the multiple moving parts, these devices begin to wear out within the first 2 years of use and the large size necessitates placement in the preperitoneal space or intraperitoneal space. The second-generation continuous flow devices are smaller and have fewer moving parts. These devices primarily consist of inflow and outflow pumps and a rotor, with a smaller conduit to the power source that does not include an air vent. Since January of 2010, 98 percent of LVADs implanted are of continuous flow design.[249] Once the device is implanted, in most cases it cannot be removed without performing concurrent cardiac transplantation.[191,239,316,315,359]

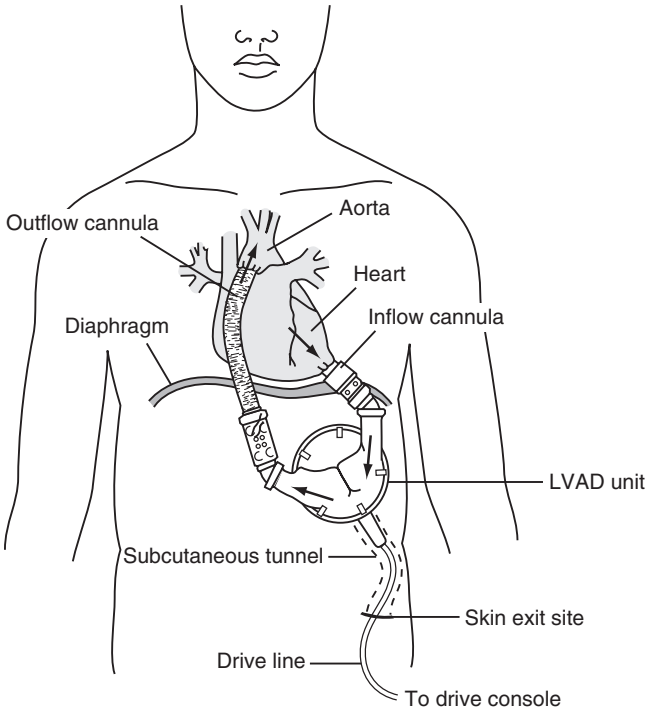

FIGURE 74-1 ■ **Left ventricular assist device.** (Modified from Fisher SA, Trenholme GM, Costanzo MR, Piccione W. Infectious complications in left ventricular assist device recipients. *Clin Infect Dis* 1997;**24**:18–23.)

Infection of an LVAD can involve any portion of the LVAD, including the surgical site, driveline, pocket, and pump. Infections occur most commonly within the first 3 months of device implantation, with the risk for severe infection and sepsis peaking at 1 month. The cumulative risk for device infection increases the longer the device remains in place; the incidence of infection significantly decreases after 3 months.[72,203,205,236] Based on data from the Interagency Registry for Mechanical Circulatory Support (INTERMACS), overall infection rates were 17.46 infections/100 patient-months during the first 12 months after implantation.[250,447,465] The rates of infection have been shown to vary among generations of device, with 28.9 infections/100 months in the pulsatile devices (n = 406) and 11.8 infections/100 months in the continuous-flow devices (n = 548) (p <.0001). It was also found that infection accounted for 16 percent of deaths associated with LVAD implantation.[203,249,419,426]

The approach taken by many centers for infection of an LVAD includes both preventive and interventional steps that are instituted before, during, and after implantation. Preventive strategies are focused on prevention of infections related primarily to the driveline and device pocket through the use of clean implantation techniques and limited traffic in the operating room in which the procedure is being performed. Antibiotic prophylaxis usually is given for 48 hours near the time of implantation of the LVAD and may include intravenous trimethoprim-sulfamethoxazole, rifampin, and fluconazole, along with the application of mupirocin ointment to the nares. Additional preventive measures include soaking the surfaces of the LVAD in vancomycin and gentamicin for 30 minutes before placing it, irrigating the device pocket with povidone-iodine (Betadine), and meticulously placing the subcutaneous tunnel in the appropriate position. Postoperative care with sterile and semisterile dressing changes around the driveline is emphasized.*

Despite the preventive measures taken, infection, thromboembolism, and hemorrhage at the time of implantation remain the most common complications associated with the use of mechanical circulatory support devices. Of these complications, infection has the most significant impact on morbidity and mortality.[153] Predisposing factors for development of device-related infections in these patients include a variety of host, device,

*References 16, 140, 204, 390, 446, 521.

and operative characteristics. Device-related risk factors are correlated with increased size and surface area of the device, turbulence of flow, contact of blood with the prosthetic surfaces, device-related pockets and cavities, transcutaneous drivelines, and power cables.[343,360] Operative and environmental risk factors include extent of surgery necessary for implantation hemorrhage, reoperation, frequent occurrence of multiple organ dysfunction or failure, duration of mechanical circulatory support, duration of hospitalization and intensive care unit stay, use of indwelling lines and catheters, parenteral nutrition, operative technique, and time.[283,391] The incidence of infection in patients on LVAD support for longer than 60 days is reported to be two times higher than that in patients with an LVAD in place for less than 30 days; initial episodes of infection after 90 days are rare.[342,384,443] With regard to patient-related risk factors, the severity of heart failure symptoms and presence of poor health and comorbid conditions, including diabetes, hyperglycemia, obesity, alcohol use, and renal disease, has been associated with increased risk for infection.[47,166,335,399,443] In addition, some evidence indicates that implantation of an LVAD itself may lead to defects in cellular immunity secondary to an aberrant state of T-cell activation that predisposes LVAD recipients to the development of candidal and other systemic infections.[18,164,217,248,384] The incidence of infection after implantation of an LVAD is reported to range between 13 and 80 percent, with most studies documenting an infection rate of 30 to 50 percent.* Most series report that the device pocket and drivelines are the device-related sites that account for most of the infections. Placement of the LVAD in the abdominal cavity instead of the preperitoneal area has been shown to decrease the chance for development of infection.[342]

Driveline infections are thought to result from a lack of integration of tissue around the driveline that allows the driveline to move and irritate surrounding tissues, which can result in an infection in the exit site and, in some cases, bacteremia. Such infections generally are defined by pain, erythema, warmth, drainage, or purulent discharge at the driveline exit site in the presence of a positive culture. Bacteremia developing after implantation of a pump and infections of the pump itself are additional reported complications.[22,317] In a study of 205 patients who underwent placement of LVADs at the Cleveland Clinic, positive blood cultures were noted in 52 percent, infections of the driveline site occurred in 22 percent, and infections of the pump pocket developed in 9.2 percent.[239] Sun and colleagues[472] reported their experience with 95 patients who underwent insertion of an LVAD. Twenty-six (27%) of these patients experienced device-related infections involving the driveline, device pocket, or blood-contacting surfaces; 15 of the 26 (57.7%) had infections of the driveline site. Persistent bacteremia and progression of infection of the device pocket and driveline site can lead to the serious infection of LVAD endocarditis, which mimics prosthetic valve endocarditis, is very difficult to treat, and is associated with a high mortality rate. LVAD endocarditis is defined as positive cultures of the LVAD surface in conjunction with clinical signs and symptoms of infection during LVAD support. Manifestations of this condition are varied and range from persistent fever and bacteremia or fungemia to cerebral thromboembolism, LVAD inlet obstruction with hemorrhage, or LVAD outflow graft rupture.[22] In a report by Weyland and associates[531] of 27 patients who underwent insertion of LVADs, infections of the driveline developed in 8 (30%) of the 27 recipients, and LVAD endocarditis, defined as positive cultures from the pump chamber, was found in 12 (44%) of the patients; 8 of the 12 (67%) died of endocarditis.

Despite a high potential for the development of serious morbidity after placement of an LVAD, studies have shown that the presence of an infection after insertion of an LVAD does not seem to have very much influence on eventual cardiac transplantation and posttransplant outcome. A study by Argenziano found that infection subsequently developed in 29 of 60 (48%) patients who underwent insertion of an LVAD.[22] The most frequent sites of infection were the blood (27%), LVAD driveline (13%), LVAD surface (13%), and central venous catheter (10%); these sites thus represented 63 percent of all infections. The overall mortality rate, the rate of successful cardiac transplantation, and the rate of infection after transplantation were not influenced by the presence of infection during LVAD support.[22] In another study, Sinha and colleagues[446] reviewed their experience with 86 patients who received LVADs; device-related infections developed in 6 patients, 5 (83%) of whom had infections of the pocket. This study also found that the presence of infection during LVAD support did not influence successful cardiac transplantation or patient survival after transplantation. Over a 6-year period, Schulman and colleagues[427] reviewed their experience with 149 patients who received LVADs as a bridge to heart transplantation and sought to determine the impact of device-related infections on posttransplant survival and posttransplant infection. Of the 149 patients, 110 were successfully bridged to cardiac transplantation. Pretransplant device-related infections (e.g., pocket infections, wound infections, and postimplant bacteremia) had no negative effect on bridging to transplantation. However, patients with pretransplant sepsis were less often successfully bridged to cardiac transplantation. The presence of a pretransplant device-related infection was found to have no effect on posttransplant 1-year survival rates, although it was associated with an increased rate of posttransplant infection, especially if the patient had a driveline infection during LVAD support. Specifically, having a driveline infection during LVAD support predisposed for having an infection in the former LVAD pocket or driveline site after cardiac transplantation, but did not predispose to having sternal wound infections, bacteremia, or sepsis in the posttransplant period. Diagnosing an infection early, determining the location and the extent of the infection, and assessing therapeutic efficacy can be a challenge in patients with LVADs. Anatomic imaging modalities such as CT and MRI may have limited value because of the presence of metallic CT artifacts and contraindications to using MRI. New imaging modalities, such as radiolabeled leukocyte single-photon emission computed tomography (SPECT/CT), are being studied to assess

*References 22, 140, 148, 203, 315, 317, 376, 472, 531.

the accuracy of these modalities in revealing both anatomic location and extent of infection in patients with an LVAD. Preliminary results of leukocyte SPECT/CT have shown it to be very accurate in diagnosing an LVAD-related infection.[68,284]

Microbiology of Left Ventricular Assist Device Infections

Numerous organisms have been isolated from LVAD infections. In most series, *S. aureus* (including methicillin-resistant strains), *S. epidermidis* and other coagulase-negative staphylococci, and *Enterococcus* spp. are the organisms most commonly isolated from these infections, usually within the first 4 weeks after implantation. Other organisms such as *Enterobacter* spp., *P. aeruginosa*, *Serratia marcescens*, *Klebsiella* spp., *Stenotrophomonas maltophilia*, *Citrobacter koseri*, other gram-negative organisms, and polymicrobial organisms were seen more commonly later in the clinical course.* Fungal infections (e.g., *Candida albicans*, *Candida parapsilosis*, *Aspergillus* spp., and *Mucor* spp.) have been reported or observed as well and were responsible for approximately 16 percent of the infections.† However, colonization with fungi occurs in 35 to 39 percent of patients with LVADs.[164] Investigators suggested that treatment with broad-spectrum antibiotics (common in these patients) rendered them more susceptible to the development of fungal infection. When a fungal LVAD infection is suspected, signs of thrush, cutaneous rashes, esophagitis, retinal changes, peripheral embolization, and unexplained decrease in LVAD output should be investigated. The presence of yeast on Gram stain of the fluid surrounding the device and ultrasound showing increasing amounts of fluid around the device can be used to help confirm the diagnosis.[164]

Management of these infections, especially LVAD endocarditis, presents a major challenge, given that the device usually cannot be removed unless simultaneous heart transplantation is performed; moreover, if transplantation is accomplished, multiple issues regarding the immunosuppressed condition of the patient are raised. In most cases, management involves a prolonged course (i.e., usually 4 to 6 weeks) of aggressive antimicrobial or antifungal therapy (or both) appropriate for the organism or organisms isolated, with meticulous attention given to skin care around the driveline exit site; débridement, drainage, surgical revision, and irrigation with povidone-iodine of infected wound sites; or in certain instances, replacement of the LVAD unit or cardiac transplantation before completing antibiotic therapy if a donor heart becomes available and all blood culture results are negative.[140,204,317]

EXTRACORPOREAL MEMBRANE OXYGENATION CIRCUITS

Extracorporeal membrane oxygenation (ECMO) is a life support device used most commonly for treating severe cardiac and pulmonary failure in neonates and children. Almost 1 percent of all children treated by open heart surgery will undergo ECMO. In addition to these post-cardiotomy patients, a growing number of children receive ECMO for acute decompensation of myocarditis or cardiomyopathy. ECMO also is used to support children after sudden cardiac arrest when conventional closed or open heart massage is unsuccessful. In children, perfusion through the neck venoarterial vessels is the preferred method, but the trans-sternal approach is used when direct decompression of the distended left ventricle is required. Although the overall survival rate of children managed by ECMO has improved in recent years, it still is only 50 to 70 percent.[35,525,536] Multiple cardiac and noncardiac factors are associated with increased morbidity and mortality rates. Patients with a single ventricle or residual cardiac defect after surgery have a less favorable ECMO outcome.[50,104,255] Renal dysfunction, multiple organ system failure, initiation of ECMO in the operating room, blood product transfusion, mediastinal bleeding, ECMO circuit problems, and duration of ECMO for longer than 10 days also were predictors of increased risk for mortality.[255,336] The infection rate for patients on ECMO ranges from 6 percent to more than 40 percent. Recent reports suggested a higher infection rate in older patients with culture-proven infections, at 6.1 to 10.1 percent in neonatal patients, 18.7 to 20.8 percent in pediatric patients, and 20.5 to 30.6 percent in adults.[49,536] Multiple risk factors for acquiring infection while on ECMO were identified, including indwelling vascular or urinary catheters,[336] duration of ECMO (>7 days),[214,468] procedures before or during ECMO,[355] ECMO complications,[64] and changes in the humoral and cellular immunity.[503] Patients with infections usually will need a longer bypass support[355] and will have a delay in post-ECMO lung recovery and increased mortality.[49,259,336]

Earlier reports suggested that gram-positive cocci (e.g., *S. aureus* and coagulase-negative staphylococci) are the most common etiologic agents. However, gram-negative bacteria (both lactose fermenting and non–lactose fermenting[214]) and fungi[193] are becoming more commonly reported. *Candida* spp. were found to be the most frequent pathogens in children and adults.[49,473] The distribution of these pathogens is similar to their distribution in other patients with infections treated in the intensive care unit.[193] The signs and symptoms of infection often are subtle and nonspecific. Fever develops in only half of these patients. The value of tachycardia and elevated cardiac output also is limited because these patients frequently are tachycardic, with increased cardiac output caused by a systemic inflammatory response (e.g., complement; cytokines such as TNF, interleukin [IL]-1, and IL-6), which is characteristic of cardiopulmonary bypass procedures.[67,332,468] For the same reason, leukocytosis (unless developing acutely) and an elevated erythrocyte sedimentation rate (ESR) should be interpreted with caution. In addition, physical examination and radiologic tests may be difficult to interpret.[67] Consequently, a high index of suspicion with careful evaluation of potential infection source (e.g., surgical wound and insertion site of catheter) and surveillance of blood and urine cultures is needed to identify these infections.

*References 22, 116, 140, 167, 204, 314, 317, 446, 486, 531.
†References 30, 112, 116, 204, 314, 366, 438.

Most patients undergoing ECMO are treated with multiple broad-spectrum antibiotics. This practice probably is one of the reasons for the increased incidence of multidrug-resistant, gram-positive (e.g., *Enterococcus*) and gram-negative bacteria, as well as fungal (e.g., *Candida*), infections. In addition, many of these patients will be colonized with these same bacteria. Therefore, if a deep bronchial suction or urine culture (performed routinely) becomes positive but without supporting evidence of infection (e.g., increased white blood cell [WBC] count, fever), serious effort to distinguish between colonization and infection should be made before initiating an unnecessary change in antimicrobial therapy. If a decision to treat is made, appropriate coverage for both gram-positive and gram-negative organisms should be chosen. If blood, urine, and bronchial cultures remain negative and the patient's condition is not improving or the culture becomes positive for a fungus, antifungal therapy should be added.

Most ECMO centers administer antibiotic prophylaxis; however, the optimal spectrum and duration of this practice are unknown. Some studies suggested that use of prophylaxis (for 24 hours before the ECMO is started) was effective in reducing infections,[65,468] others found no correlation between antibiotic prophylaxis and reduction in infection rate.[214] Of interest, despite advances in critical care for ECMO patients (including antibiotic prophylaxis) no significant decrease has occurred in infection rate during the last two decades.[64] The lack of specific guidelines and evidence from randomized trials evaluating different durations and spectrums of antibiotic contribute to the confusion and controversy in this area.[235] If prophylaxis is considered, antifungal prophylaxis (e.g., fluconazole) should be added because it was shown to decrease the incidence of fungal infections, which are increasing.[154]

PERMANENT CARDIAC PACEMAKER AND IMPLANTABLE CARDIOVERTER-DEFIBRILLATOR INFECTIONS

Permanent Cardiac Pacemaker Infections

Cardiac pacemakers have been widely used since the 1980s and the American Heart Association (AHA) has recently expanded the indications for their use.[129] Two types of permanent pacemaker generators are in use; those with transvenous electrodes and those with epicardial electrodes. Both types are implanted in either the chest or the abdominal wall; pacemakers with epicardial electrodes are the ones more commonly used in the pediatric population.

Infection is one of the most common medical complications of implantation of permanent pacemakers, with reported rates ranging from 0.2 to 5.8 percent and a high mortality rate.[70,86,518] An estimated 25 percent of cardiac pacemaker–associated infections develop within 1 to 2 months of placement of the device, but delays of up to 12 months may occur before diagnosis is established. Several studies suggested that the relative rate of infection associated with permanent pacemakers has increased despite improved surgical techniques and better design of the devices themselves,[70,502,518] but a recent study demonstrated a fairly constant rate of infection over 20 years.[226] Studies have shown that infections of permanent cardiac pacemakers seem to occur more commonly in patients with both local and systemic underlying medical problems, especially diabetes mellitus or an underlying renal insufficiency, or in those who are undergoing treatment with corticosteroids, anticoagulants, or other types of immunosuppressive therapy.[51,452,518] Other well-characterized independent risk factors include surgery related to any part of the pacemaker (especially replacement of a battery or upgrade of the pacemaker),* the presence of a hematoma after implantation,[71,347,451] temporary transvenous pacing[194] and epicardial leads.[451] Multiple (two or more) pacemaker insertions and physician inexperience with insertion also represent significant risks for development of infection.[185,347] The presence of a central venous line also increases the risk for systemic infection.[76] Multivariable analysis of the largest reported pediatric pacemaker infections identified only presence of Down syndrome and manipulations of the pacing system during revisions as risk factors.[94]

Infections of permanent cardiac pacemakers are subdivided into groups depending on the specific site of involvement and whether they are early infections (<1 to 2 months after implantation) or late infections (>2 months after implantation). The groups are (1) local inflammation, infection, and the formation of an abscess in the generator pocket or subcutaneous portion of the lead, or in both sites; (2) secondary infection involving either the generator or the electrodes (including pacemaker endocarditis)[71,124]; (3) fever plus associated bacteremia, with or without concomitant infective endocarditis, in a patient without any apparent focus of infection[124]; and (4) mediastinitis, pericarditis, bronchopleural cutaneous fistulas, and mixed infections.[124]

The generator pocket and the subcutaneous portions of the leads (i.e., transvenous and epicardial) are the most common sites of infection. Infections of the pocket often are difficult to diagnose and may develop at any time after implantation; however, most tend to develop early and frequently are the result of contamination by skin flora at the time of the procedure.[333] Late infection usually occurs as a consequence of erosion of the device through the subcutaneous tissue and skin. The infection may remain localized to the pocket or may spread to the adjacent electrodes and lead to the development of bacteremia. Infection of transvenous pacemaker leads may occur in as many as 17 percent of patients who receive permanent pacemakers. These infections often are not apparent initially but have been associated with significant morbidity and mortality.[175] Infection generally develops along the subcutaneous portion of the leads and, if unrecognized, may progress centrally and result in sustained bacteremia, endocarditis, or both. Infections of the leads tend to occur later than infections of the pocket, with the median time of occurrence being 7 to 8 months after implantation of the pacemaker. Endocarditis as a

*References 76, 185, 194, 226, 265, 347.

complication of unrecognized infected transvenous leads can develop years (2 to 3 years) after placement of the pacemaker. Infections of permanent epicardial leads generally occur as a complication of infections of the generator pocket, skin erosion, or direct contamination at the time of placement. However, in contrast to infections of the transvenous leads, infections of the epicardial leads usually result in only local symptoms; rarely, they may lead to more severe disseminated disease such as pericarditis, mediastinitis, bronchopleural cutaneous fistulas, bacteremia, or sepsis.

Microbiology

Staphylococci (*S. aureus* and coagulase-negative staphylococci) are the most common causes of pacemaker-related infections, accounting for more than 85 percent of such infections; however, a wide variety of organisms have been isolated.* An increasing number of the isolated staphylococci are methicillin-resistant. Other gram-positive organisms such as viridans streptococci, other streptococci, enterococci, *Listeria*, and *Corynebacteria* have been isolated as well, but each causes fewer than 1 percent of cases. Gram-negative organisms such as *E. coli*, *Proteus*, *Enterobacter cloacae*, *P. aeruginosa*, *Klebsiella*, and *S. marcescens* are isolated from 5 to 20 percent of device-related infections. In addition, *Candida*, *Aspergillus*, *Pseudallescheria*, and other fungi have been isolated rarely as well as *Mycobacterium* spp.; however, infections with these organisms generally are associated with poor clinical outcomes.†

Clinical and Laboratory Findings

Diagnosing a pacemaker-associated infection can be difficult because of its nonspecific symptomatology, and months may elapse after the onset of symptoms before the diagnosis is established. Symptoms may be confined to a local area or may be more widespread, with the development of bacteremia or other systemic effects. Rarely, the only sign of infection is persistent pain at the pocket site.[254] Fever (84% to 100%) and chills (75% to 84%) are considered the most common systemic symptoms and are indicators of local infection, especially if they occur after the second postoperative day in association with other signs; however, they may be the only clinical manifestation in more than a third of patients.[71,253,334,353,535] Early infections are more likely to be accompanied by both local and systemic clinical findings and are manifested more commonly as infections of the generator pocket, bacteremia, or septicemia[71,294,557]; late infections, on the other hand, typically cause vague symptoms that evolve over the course of time and usually are lead-related infections and endocarditis.[265,513]

Infections of the generator pocket typically cause local swelling (21%), erythema (34%), pain (32%), drainage (through an incompletely healed incision or fistulous tract) over or adjacent to the generator pocket (25%), and warmth (11.5%).[86] Sterile breakdown of the pacemaker pocket develops in an estimated 5 percent of patients with permanent pacemakers, and skin or soft tissue erosion over the electrodes occurs in an additional 2 to 4 percent. Because these complications are associated with a high risk for the subsequent development of infections, the presence of any erosion is considered a potential indicator of device-related infection, especially if the erosion occurs more than 24 months after placement of the pacemaker, at which time the infection rate may be as high as 80 percent.[46,174] Pacemaker-related endocarditis is a relatively rare complication that occurs in 0.05 to 0.5 percent of cases after implantation of a pacemaker. Such endocarditis is associated with a mortality rate as high as 34 percent in some series.[71,152,253] It tends to be a late complication; only 27 to 36 percent of patients are seen within 6 to 12 weeks after the last procedure at the pacemaker implant site, with symptoms developing in most patients a mean of 25 months after the last procedure at the implant site. The diagnosis of pacemaker-related endocarditis is difficult to establish, and usually a delay in making the diagnosis, with a mean interval of 5 to 8 months after the onset of symptoms, occurs.[71,253] Pulmonary symptoms are found in 20 to 45 percent of patients with pacemaker-related infections and may consist of bronchitis, lung abscess, pneumonia, or pulmonary embolism; these symptoms are seen more commonly in late-onset infection and in patients with intravenous lead–related infection.[71,253]

A variety of laboratory and imaging studies may be performed to aid in establishing the diagnosis of a pacemaker-related infection. A recent update from the AHA suggested two sets of cultures from blood, generator pocket site, and lead tips when infection is suspected.[29] An elevated ESR is found in 82 to 97 percent of patients, and peripheral leukocytosis is seen in 50 to 66 percent. The presence of a collection of fluid around the device as seen on ultrasound is suggestive of device-related infection. Gallium scanning may be performed in an attempt to determine the nature of the fluid (i.e., inflammatory vs. infectious). Transesophageal echocardiography (TEE) can be helpful in identifying endocarditis (especially when blood culture results are negative). TEE has emerged as a major tool in diagnosis; studies have shown that this test was able to demonstrate vegetations and other lesions on the electrodes, ventricular endocardium, and tricuspid valve in 90 to 96 percent of patients with pacemaker-related infections.[71,253,513] Only the combination of negative TEE and ECHO should be used to rule out endocarditis.[453]

Management and Treatment of Infection

Appropriate therapy for pacemaker-related infections is tailored to the specific clinical situation and depends on several factors: (1) whether the infection is limited to the generator pocket or subcutaneous electrodes, without bacteremia; (2) whether bacteremic pacemaker-related endocarditis is present with or without involvement of the subcutaneous electrodes; and (3) what organism is involved.

*References 71, 76, 309, 347, 451, 453, 513.
†References 10, 71, 82, 85, 237, 264, 270, 301, 453, 513, 535.

If the infection is limited to the generator pocket or subcutaneous electrodes, optimal treatment consists of both medical and surgical intervention in which all of the parts of the infected device are removed. Studies have shown that failure to remove completely all portions of the infected device results not only in failure to cure the infection but also in higher mortality rates.[29,71,517] In addition, infection relapse is higher.[86,305,452] The patient is given parenteral antimicrobial therapy, and an exchange of the pacing system with total removal of the infected device and simultaneous insertion of a new pacemaker at a different site is performed surgically. The infected subcutaneous pocket is drained, débrided, and packed open, and local wound care is instituted. Initial antibiotic therapy should provide coverage for both staphylococci and gram-negative bacteria; therapy is tailored once the organism is identified and its antibiotic susceptibility is known. Initial regimens include vancomycin plus an aminoglycoside. Oxacillin or nafcillin plus an aminoglycoside may be used if MRSA is rare in the community. In certain instances, a new pacemaker cannot be placed at the time of removal of the infected device; in such situations, a period of temporary transvenous pacing is instituted until a new pacemaker can be implanted. For local pocket infections, antimicrobial therapy targeted at the causative organism should be administered for 10 to 14 days.

The consensus approach to the management of pacemaker-related endocarditis and bacteremia involves removal of both the generator unit and the electrodes in conjunction with prolonged administration of parenteral antibiotic therapy designed to treat endocarditis (usual duration, 4 weeks).[29,452] In cases of MRSA, duration of treatment should be extended to 6 weeks.[285] A longer duration may be considered in patients with other sites of infection (e.g., osteomyelitis or septic thrombophlebitis). Vancomycin should be the initial antimicrobial treatment of choice before the etiologic agent is identified, because the majority of infections are due to staphylococci species. More specific antibiotic regimens can be used when the pathogen is identified and in vitro susceptibility is available. Mortality rates may be as high as 50 percent for patients in whom total removal of the pacemaker unit is not performed.[71,253,375] Percutaneous removal of electrodes that have lead-associated vegetations smaller than 20 mm is acceptable,[29,139] but extraction of the electrodes with vegetations larger than 20 mm may be difficult and risky to perform, and surgical removal by cardiotomy may be necessary.[29] In patients who require a pacemaker, temporary transvenous pacing may be implemented until a new permanent pacemaker can be placed. Sterility of blood cultures should be ensured before a new pacemaker generator and electrode are placed.

Infection of Implantable Cardioverter-Defibrillators

The first implantable cardioverter-defibrillator (ICD) was placed in 1980, and during the last several decades the device has become a successful therapeutic modality for treatment of patients (both adults and children) with life-threatening ventricular arrhythmias. Older devices required surgical placement of a pulse generator, extrapericardial or epicardial defibrillation patches, and a transvenous rate-sensing electrode. The systems placed today use a rate-sensing lead that is implanted transvenously, a superior vena cava coil electrode, and additional subcutaneous or epicardial electrodes all connected to a pulse generator that is placed subcutaneously or submuscularly.[241,461,539]

Infection is the most serious complication of placement of an ICD.[71,267] Infection rates associated with placement of ICDs ranged from 1 to 7 percent.[462,490] However, infection rates have decreased substantially with the advent of transvenous non–thoracotomy-placed systems, with rates ranging from 0.8 to 1.5 percent.* Cost associated with hospital admission, length of stay, and mortality are substantially increased in patients with infection in contrast to those without it.[450] Several risk factors that have been identified as increasing the likelihood for development of infection include steroid use, diabetes, heart failure, and renal failure.[51] Previous generator replacement, use of anticoagulants, abdominal implantation, postoperative hematoma, and surgeon experience also were reported as contributing to increased risk for infection.[51,275,501] Most ICD-related infections are clinically apparent within 3 to 6 months after placement, with infections of the generator pocket, subcutaneous patch wound site, epicardial patches, or bacteremia and endocarditis being the most common manifestations. Some infections can be indolent, and only a high index of suspicion will initiate an investigation. An increased WBC count and ESR, anemia, and microscopic hematuria are the most common laboratory findings. As with pacemaker infections, TEE is an effective test to exclude endocarditis because echocardiography is helpful in only half of the cases.[146] Infection of the generator pocket or subcutaneous patch wound site usually causes local findings of pain, erythema, and collection and drainage of fluid from the site. Occasionally, these patients also may be bacteremic or hypotensive. In contrast, infection of the epicardial patches generally results in more systemic symptoms, bacteremia, or pericarditis.[357] At least two blood cultures should be obtained to rule out bacteremia. Cultures of the generator pocket and lead tips after removal of the device are essential for identifying the pathogen. Sonication of the extracted device increases the yield of positive cultures.[308]

Microbiology

S. aureus and coagulase-negative streptococci are the major pathogens seen with ICD-related infections and account for 60 to 80 percent of cases.[267,357,416,462,515] However, a broad spectrum of other gram-positive, gram-negative, and fungal organisms, including *P. aeruginosa*, *Corynebacterium*, streptococci, *E. coli*, *Klebsiella*, *Bacteroides fragilis*, *Propionibacterium acnes*, atypical mycobacteria, and *Candida* spp., have been isolated from ICD-related infections. Polymicrobial infections may occur in the generator pocket.[267,416,449]

*References 163, 326, 357, 449, 501, 529.

Management

The same approach as was previously described for pacemaker infection should be applied to ICD infection. To eliminate ICD-related infections effectively, optimal management involves a combination of medical and surgical interventions, especially if the patient is bacteremic or has systemic findings or if the causative organism is *S. aureus*. Several studies have suggested that conservative management (i.e., antibiotic therapy without removal of the hardware) may be sufficient. However, such an approach should be tried only in cases with superficial or incisional infection and in rare occasions when only the generator pocket is infected or in patients whose condition prevents removal of the entire device. In these cases, the management should consist of administration of parenteral antibiotics, wound care, and removal of only the generator portion of the device with implantation of another generator at a different site.[357,497] The optimal management of any other ICD-related infection is parenteral antibiotics and complete removal of the entire ICD system, followed by reimplantation (after the infection is eradicated) at another site.[86,267,416,537] Although no data exist on the optimal duration of appropriate antibiotic therapy, at least 2 weeks should be considered, and if blood cultures continue to be positive 24 hours after removal of the ICD, a longer period (e.g., 4 weeks) should be considered. For infections limited to the pocket site, 7 to 10 days of appropriate antibiotics may be sufficient.

PROSTHETIC JOINT AND ORTHOPEDIC IMPLANT INFECTIONS

The implantation of prosthetic joints along with the use of other implantable orthopedic devices (e.g., pins, screws, plates, rods, external fixators, or Ilizarov apparatus) has improved quality of life greatly and restored function to patients suffering from debilitating bone and joint disease, tumor, or injury. Based on conservative estimates, millions of people worldwide have some form of prosthetic joint or other implantable orthopedic device. Of the possible complications associated with implantation, infection is the second most common cause of prosthetic joint failure.[17] It occurs in 0.6 to 2.4 percent of total joint replacement[123] and results in postoperative prosthesis failure, chronic pain, immobility, and, in some cases, loss of the affected limb or, in the worst-case scenario, loss of life.[4,42,119,467] The health care cost in the United States for treating a single infection of a prosthetic joint is estimated to be more than $280 million per year nationwide.[190] The number of prosthetic joint infections is increasing.[263]

Prosthetic joints and implantable orthopedic devices may become infected by two major mechanisms: (1) the prosthetic device may be contaminated by microorganisms at the time of implantation, either as a result of airborne contamination in the operating room or by direct inoculation at the time of surgery; or (2) the prosthetic device may become infected as a result of hematogenous seeding from bacteremia or by direct contiguous spread from an infection adjacent to the prosthesis. Of infections of prosthetic joints, 20 to 40 percent arise by hematogenous seeding, with the remainder occurring as a result of airborne or direct inoculation.[3,281,282] Infections may remain asymptomatic for years before symptoms become apparent, and usually a long delay occurs between onset of the infection and the appearance of symptoms and confirmation of the diagnosis. The overall rate of infection of prosthetic joints has been shown to be highest in the first 6 months postoperatively, with a steady decline occurring after this time. The incidence rate for infection of total hip and total knee arthroplasties during the first 2 years postoperatively is reported to be 5.9 infections/1000 joint-years; in contrast, during postoperative years 2 to 10, it is 2.3 infections/1000 joint-years.[466] The risk for acquiring infection and the incidence of infection depend on the anatomic location of the implanted orthopedic device or prosthetic joint, with the hips having the highest risk, followed in descending order by the knees, elbows, shoulders, wrists, and ankles.[91,395,469] For implantable orthopedic devices, rates of infection range from 2 to 30 percent.[299,511]

Risk Factors

Numerous factors have been identified as increasing a patient's risk for developing infection of a prosthetic joint or orthopedic implant, including rheumatoid arthritis, diabetes mellitus, obesity, poor nutritional status, use of steroids, immunocompromised status, psoriasis, hemophilia, sickle-cell hemoglobinopathy, solid-organ transplant, dialysis-dependent renal failure, joint dislocation, and extremes of age.[42,110,184,364,536] In addition, procedure-related factors such as previous surgery at the site of the prosthesis or implant, extended operation time (>2.5 hours), postoperative bleeding, and hematoma also increase the risk for acquiring an infection.[110,368,544] The relative risk for the development of prosthesis-related infections in patients with poor healing and wound complications increases from 13- to 20-fold after total-knee replacement and from 22- to 52-fold after total-hip replacement.[544] in addition, bacteremia from any source increases the risk for prosthesis infection.[556] For example, prosthesis-related infection developed in 34 percent of patients with *S. aureus* bacteremia who were followed prospectively.[340]

The implanted metal prosthetic device and the PMMA cement that binds the prosthetic device to adjacent bone also predispose the joint space and bone to infectious processes, given that both are foreign bodies. In vitro studies have shown that the unpolymerized form of PMMA cement predisposes to infection by inhibiting phagocytic, lymphocytic, and complement function; the risk for acquiring infection seems to be enhanced further once the cement has polymerized in the body.[379,380] Cementless prostheses have been designed in an attempt to overcome the problem of infection associated with the PMMA cement. For certain orthopedic implants, the integrity of the skin is compromised chronically, thus providing ready access to organisms from the external environment.

Microbiology

Although any microorganism can cause prosthetic joint infections, more than half of the infections are caused by *S. aureus* or coagulase-negative staphylococci.[110,556] Other gram-positive bacteria (e.g., β-hemolytic streptococci, viridans streptococci, and enterococci) cause 20 to 25 percent of infections. Antibiotic resistance in these organisms is increasing, and multiple strains of staphylococci may be present in a single prosthetic joint infection.[223,299,417,511,540] Less commonly, aerobic gram-negative bacilli, including *E. coli*, *Proteus mirabilis*, *Klebsiella* spp., *Salmonella* spp., *S. marcescens*, other Enterobacteriaceae, and *P. aeruginosa*, may cause infection. In addition, 4 to 10 percent of infections are caused by anaerobic organisms such as peptostreptococci and *Bacteroides* spp.; polymicrobial infections occur in approximately 10 percent of cases, with *S. aureus* and anaerobes the most frequently found.[304] Infections with fungi, particularly *Candida*, *Aspergillus*, and *Penicillium* spp., or with mycobacteria (i.e., *Mycobacterium tuberculosis*, *Mycobacterium avium* complex [MAC], and other rapidly growing mycobacteria) also have been described.[28,41,302,495] Rarely, a wide spectrum of other organisms, including *Corynebacterium*, *Propionibacterium*, *Bacillus* spp., and *Mycoplasma hominis*, have been reported to cause infection. Zoonotic bacteria such as *Brucella* spp., *Yersinia* spp., and *Pasteurella* spp. rarely can cause infection and should be considered in the correct epidemiologic setting.[302] Approximately 10 percent of infections are culture negative.

Certain clinical situations may predispose a patient to particular organisms as the cause of infection. Pyogenic skin infections commonly result in staphylococcal and streptococcal infections of prosthetic joints, whereas infections of the teeth and gums are frequent causes of viridans streptococcal and anaerobic infections in prostheses. Genitourinary and gastrointestinal tract procedures or infections frequently are associated with enterococcal and gram-negative bacillary infections of prostheses. The increased use of TNF-α blockers in patients with joint prosthesis predisposes them to infections with unusual pathogens (e.g., fungi or mycobacteria).

Clinical Manifestations

The clinical findings and severity of symptoms seen with infections of prosthetic joints are highly variable and determined primarily by three factors: (1) the route of infection—the hematogenous route versus direct inoculation; (2) the virulence of the infecting pathogen—*S. aureus* and, to a lesser extent, β-hemolytic streptococci and gram-negative bacilli seem to be particularly virulent pathogens capable of producing a fulminant clinical picture, whereas infection with organisms such as coagulase-negative streptococci is associated with a more chronic, indolent course; and (3) the nature of the tissue in which the microorganism proliferates—hematomas, seromas, ischemic wounds, and the tissues of diabetic patients and those receiving steroids all enhance the ability of the bacteria to proliferate and spread, thereby promoting the development of a more deep-seated fulminant infection.

The most common initial symptom is joint pain, which occurs in 95 percent of cases. Such pain can range from an acute fulminant illness with erythema, severe joint pain, swelling (38%), high fever (43%), and systemic symptoms to a chronic, slowly increasing pain in the joint without typical signs of inflammation that may be associated with the formation of a cutaneous draining sinus (32%) but no systemic symptoms.[110,556] The presence of constant joint pain is more indicative of infection than is the presence of pain occurring only with movement or weight bearing, which is more common in aseptic and mechanical complications.

For implantable orthopedic devices, the most common initial symptom of infection is erythema, swelling, pain, or drainage from the area around and adjacent to the implant. Local symptoms also may be associated with fever, especially if the device is extensive or deep-seated.

Diagnostic Studies

Laboratory screening tests commonly used to diagnose infection of a prosthetic joint or implanted orthopedic device such as peripheral WBC count, C-reactive protein (CRP), and ESR are neither specific nor sensitive (sensitivity 60% to 96% and specificity 55% to 92%).[110,459] Of these tests, CRP seems to be the better test. These test results may be normal, especially in patients with chronic, slowly progressing infection. Several biomarkers (e.g., procalcitonin, TNF, and IL-6[43,434]) have been suggested as diagnostic tests. Molecular techniques such as polymerase chain reaction (PCR), fluorescence in situ hybridization (FISH) and immunofluorescent microscopy were reported to have a sensitivity of 63 to 100 percent in detecting bacteria in prosthetic joint infections[196,306] but were not studied widely.[12,320]

The principal radiologic studies used for detection of an infected prosthetic joint include plain radiographs, arthrograms or sinograms, and radioisotope scans (indium and technetium diphosphate). Abnormalities that may be suggestive of infection and can be seen on plain radiographs include radiolucency at the bone–cement interface, motion and changes in position of the prosthetic components, evidence of osteomyelitis, cement fractures, and periosteal reaction. Intra-articular injection of dye (arthrogram or sinogram—in the presence of a sinus tract) may demonstrate abnormal communication between the joint space and the bone–cement interface. These radiographic abnormalities are present in approximately 50 percent of infected prostheses.[101,297] Nuclear scans with indium-111–labeled WBC or technetium-labeled sulfur colloid (^{99m}Tc) may be used to detect periprosthetic inflammation. Scanning techniques have a sensitivity of 80 to 86 percent and a specificity of 94 to 100 percent.[362,481] Of note, increased uptake can be seen around uninfected prostheses within the first 6 to 12 months after implantation. Therefore, positive findings after this time are abnormal and reflect inflammation (which could be due to a variety of causes) but not specifically infection.[122,200,234,358] Of interest, ^{99m}Tc-labeled ciprofloxacin (which probably binds to live bacteria at the infection site) was shown to be 94 percent sensitive and

83 percent specific for diagnosis of chronic infection.[456] Use of this technique allowed 11/12 infections of prosthetic joints to be identified, whereas ^{99m}Tc-WBC scintigraphy was positive in only seven patients.[457] Combining antigranulocyte antibody (^{99m}Tc sulesomab) and ^{99m}Tc collodial rhenium sulfide (nanocolloids) was shown to be an acceptable alternative.[458] Positron emission tomography with fludeoxyglucose F-18 (18 FP-FDG PET) was also evaluated as a diagnostic technique.[110,266,471] CT and MRI are not used routinely in the evaluation of patients with suspected infection of a prosthetic implant because of the large amount of imaging artifact created by prosthetic devices.[58,331]

Aspiration of joint fluid for culture and culture of tissue obtained intraoperatively are the optimal ways to establish a specific diagnosis of infection of a prosthetic joint. Unfortunately, the yield is only 50 to 90 percent. To optimize the yield, antibiotics should be stopped 2 to 3 days before aspiration or operative cultures are taken.[556] Although joint fluid findings indicative of an infectious process are a high leukocyte count (consisting mainly of polymorphonuclear leukocytes [PMNs]), a high protein content, and a low glucose concentration, these changes are not specific for bacterial infection and are present in only some patients. Using a cutoff value of 1700 WBC/μL with at least 65 percent PMN cells gave excellent results.[488] The fluid obtained should be cultured for a variety of organisms; Gram stain is positive in a third of cases, and a causative pathogen can be identified in only two thirds of patients.[375,460] Intraoperative cultures should include, if possible, any purulent discharge, devitalized bone, and tissue from the bone–cement interface. Vortexing, bath sonication, or both of the explanted prosthesis may increase the yield.[369] Histopathologic examination of this tissue usually reveals an infiltration of PMNs consistent with an acute inflammatory reaction but not specific for infection.[176,489] More rapid, specific, and sensitive tests (e.g., FISH, PCR, immunofluorescent microscopy) are needed to differentiate between noninfectious inflammation and bacterial infection and identify the pathogen in patients already receiving antibiotic or infected with fastidious pathogens.

Treatment

Successful treatment of an infected prosthetic joint involves extensive surgical débridement of all devitalized bone and tissue, removal of the prosthesis and all associated cement, and prolonged parenteral antibiotic therapy.[33,89] For optimal results, the débridement should be performed within 1 to 3 weeks.[110,271,303] Microbiologic cure has been found to correlate well with the extent of débridement and the completeness of removal of all residual methylmethacrylate cement. Historically, attempts at simple surgical débridement without removal of the prosthetic device in conjunction with parenteral antibiotic therapy had variable success, with relapse rates being as high as 88 percent by 2 to 4 years after therapy.[141,422,537] High failure rate was reported in *S. aureus* infections,[60,514] but in patients with a short duration of prosthetic joint infection caused by penicillin-susceptible streptococci, débridement and antibiotic therapy alone appear to be sufficient, with a low risk for relapse.[325]

Two protocols have been used for the treatment of these infections. A two-stage surgical procedure with prolonged parenteral antibiotic therapy has been shown to be one of the most successful treatment regimens with the best functional results. The first stage involves complete removal of the prosthesis and cement followed by a 6-week regimen of antibiotic therapy empirically chosen to cover the most likely organism and then tailored once the organism has been identified and its antibiotic susceptibility is known. The second stage involves reimplantation of a new prosthetic device at the end of the antibiotic course. Success rates with this procedure range from 87 to 100 percent.[138,278] An alternative method of therapy involves a one-stage exchange operation in which the infected prosthetic device and cement are removed, all devitalized tissue and bone are débrided, and a new prosthesis is reimplanted immediately, followed by 6 weeks of parenteral antibiotic therapy. Antibiotic-impregnated (i.e., tobramycin or gentamicin) methylmethacrylate cement is used in these situations, and success rates of more than 75 percent were reported.* This procedure is appropriate only for patients with infections caused by less virulent microorganisms because of the high failure rates seen when a more virulent organism such as *S. aureus* or a gram-negative bacillus is the cause of the infection. The Ilizarov method allows simultaneous treatment of infection, bone and joint deformities, bone loss, and shortening of the limb. This device includes proximal and distal circular external rings with wires passing through the bone and soft tissue from one side of the limb to the other. Although this method is used more often for the treatment of bone nonunion or bone loss with or without infection, David and colleagues[109] used this technique successfully to treat 12 patients who failed total-knee arthroplasty because of infection. Wound infection and chronic osteomyelitis caused by infection of the wire tract occur infrequently and should be treated by débridement of the infected soft tissue and curettage of the infected bone.

The two-stage prosthetic removal-reimplantation procedure coupled with the incorporation of antibiotic-impregnated cement during reinsertion of the implant, in combination with a 6-week antibiotic regimen, is the mainstay of therapy for infections of prosthetic joints. Selection of antibiotics should take into account the recent increase in methicillin resistance among staphylococci for the following reasons: MRSA infections of the prosthetic joint result in a higher incidence of treatment failure than do infections with methicillin-susceptible *S. aureus*, and the former result in longer durations of hospitalization and a low survival rate free of treatment failure.[412] Thus, vancomycin (with or without rifampin) should be the initial drug of choice for gram-positive bacteria until the susceptibility of the infecting organism is known.[457] In chronic and hematogenous infections (in which gram-negative bacteria are more common) carbapenems, aminoglycosides, or fluoroquinolones should be considered in addition to vancomycin until the

*References 74, 126, 127, 184, 373, 398, 500, 556.

microbiology results are available. Reports of treatment failures (even with vancomycin susceptibility within the treatment range [i.e., 2 to 4 μg/mL])[213,482] suggest that other antibiotics (e.g., trimethoprim-sulfamethoxazole or linezolid) should be considered. Several reports have shown that linezolid is a reasonable alternative that results in control of the infection.[328,510]

For infected implanted orthopedic devices, the success of therapy is based on total removal of the device together with parenteral antibiotic therapy. In cases in which the foreign body cannot be removed, extended parenteral antibiotic therapy should be instituted and continued until the device can be removed. The duration of therapy varies with the severity of the infection and ranges from several weeks to several years.

Prevention

Like other surgical procedures, prevention efforts should be focused on reducing the ability of the pathogen to reach the surgical site.[16] Patients should be screened for *S. aureus* colonization, and efforts should be made to decolonize those found to be carriers. The success of intranasal mupiricin or bathing with chlorhexidine in reducing the rate of surgical site infections suggests that such measures should be considered for patients receiving prosthetic joint or other implantable orthopedic devices.[53,377]

The use of prophylactic antibiotics for dental procedures in patients with an orthopedic device is controversial. Although no evidence supports such prophylaxis,[44] the American Academy of Orthopedic Surgery recommended it for all patients with joint implants.[13] The practice of using antimicrobial-loaded bone cements for prophylaxis is also controversial. Retrospective studies found it to be effective, but prospective studies found no extra benefit compared to systemic antibiotic prophylaxis.

CENTRAL NERVOUS SYSTEM SHUNTS

Infection is a major cause of morbidity in children who undergo CSF shunting procedures.[243,260,444] Such procedures are performed to divert CSF in symptomatic hydrocephalic patients and are used commonly in patients with anatomic abnormalities (e.g., meningomyelocele and Chiari malformations), in premature newborns with intraventricular hemorrhage or intracranial infections (e.g., congenital cytomegalovirus, congenital toxoplasmosis, and bacterial meningitis), and in patients with central nervous system (CNS) tumors or head trauma. Usually, the proximal end of the shunt is placed in the frontal or fourth ventricle and the distal end is inserted into the peritoneal cavity (i.e., ventriculoperitoneal shunt). Other compartments such as the right atrium (i.e., ventriculoatrial shunt), the pleural cavity, or the gallbladder can be used to place the distal end. CSF shunts are prone to complications, with a 10-year failure rate greater than 50 percent.[117] The most common complication is mechanical (such as obstruction or overdrainage from siphoning), followed by shunt-related infection. The incidence of shunt-related infection varies considerably, from 0.3 to 26 percent.[66,99,132,182,243,260,444] These infections increase morbidity rates and, in some cases, significantly affect patient outcomes. In addition, the increased morbidity caused additional expenses and resulted in higher costs to the health care system.[496] Understanding some of the factors that contribute to the development of these infections has helped reduce their incidence.[136,526]

Epidemiology

Almost two thirds of shunt-related infections occur within 1 month after placement of the shunt, and 90 percent of infections are manifested within 6 months.[181,257,321,428] The incidence of shunt-related infections is significantly higher in infants in the first 6 months of life than in older children or adults.[128,269,382,516] The infection rate is even higher in newborns with intraventricular hemorrhage who undergo shunting in the first week of life[14] and in premature infants.[260,322] Reasons for the increased incidence of shunt-related infection in very young patients are multifactorial. Several mechanisms that have been suggested include delayed wound healing, higher skin density of bacteria that are more resistant to antibiotics and more adherent to the shunt than in older children, longer duration of hospitalization, surgical technique, and increased exposure to antibiotics just before the shunt is placed.

No significant difference in infection rate is seen in patients with ventriculoperitoneal or ventriculoatrial shunts,[354,441] but a lower infection rate was noted in those with lumboperitoneal or cholecystic shunts. An increased risk for development of infection was reported for shunts placed immediately after removal of a previously infected shunt, probably because of incomplete eradication of bacteria.[131,246] Several other factors, including the underlying cause of the hydrocephalus,[128] the surgeon's experience,[92,242] previous shunt infection,[315] the duration of surgery, the number of people in the operating room, operative technique (e.g., prophylactic antibiotics, skin preparation, and shaveless operation),[210] operative time, open surgery to insert the abdominal catheter versus direct puncture of the abdominal wall with a trocar, postoperative CSF leakage, and others,[260,444] have been reported to be associated with an increased incidence of shunt-related infection. Although a trend toward more shunt-related infections has been reported with these factors, it has not been demonstrated consistently. A few studies suggest that tapping the shunt may result in an infection, with an incidence ranging from negligible to greater than 30 percent in premature infants with shunts tapped multiple times.[66] Reinfection rate was estimated to be around 25 percent.[243,261,493] Multiple factors were suggested as contributing to reinfection, including treatment duration of the first infection, age younger than 6 months, male sex, nonsurgical management, intraventricular hemorrhage (IVH) of prematurity, intracranial cysts, or aqueductal stenosis.[322,444,493] The median time to reinfection (i.e., second episode) ranged from 65 to 90 days.[261,493] Almost 60 percent of children with second infection developed a third reinfection, and 47 percent of

TABLE 74-2 **Pathogens Causing Cerebrospinal Fluid Shunt Infection**

Pathogens	Incidence (%)
Gram-Positive Bacteria	
Staphylococcus, coagulase-negative (e.g., *Staphylococcus epidermidis, Staphylococcus capitis, Staphylococcus hominis, Staphylococcus warneri, Staphylococcus lugdunensis, Staphylococcus haemolyticus*)	25-70
Staphylococcus aureus	10-40
Streptococci (e.g., *Streptococcus pyogenes,* group B or C streptococci, *Enterococcus, Streptococcus pneumoniae*)	3-7
Propionibacterium spp.	Rare
Corynebacterium spp.	1-2
Gram-Negative Bacteria	
Escherichia coli	5-25
Klebsiella spp.	5-10
Proteus spp.	2-6
Pseudomonas spp.	2-4
Acinetobacter spp.	1-3
Other gram-negative bacteria (e.g., *Neisseria* spp., *Haemophilus influenzae, Pasteurella*)	<1
Fungi	<1
Candida spp.	
Histoplasma	
Cryptococcus	
Torulopsis	

them developed a fourth infection.[494] The median time to the second infection was 65 days, for the third infection 477 days, and for the fourth infection 2137 days.[493]

Etiology

Staphylococcal species are the most common cause of shunt-related infection, with coagulase-negative staphylococci (e.g., *S. epidermidis*, *Staphylococcus capitis*, *Staphylococcus hominis*, and *Staphylococcus lugdunensis*)[125] being isolated in 25 to 70 percent of cases (Table 74-2).[125,254,269,441] *S. aureus*, the second most common gram-positive bacterium, is responsible for 10 to 40 percent of cases. Streptococci (e.g., viridans, group B or C, *S. pyogenes*, *S. pneumoniae*, enterococci) are identified less commonly (3% to 7%). Other gram-positive bacteria such as *Propionibacterium*[269,485] and *Corynebacterium* (diphtheroids)[23,173] are isolated as well. The seemingly increased incidence of shunt-related infections caused by these two groups of bacteria probably is the result of poor culture technique (e.g., failure to use anaerobic culture media, less than 5 to 7 days' incubation period), misinterpretation of culture results (e.g., culture contamination) leading to underreporting, or both.

Gram-negative bacteria (e.g., *E. coli*, *Klebsiella* spp., and *Proteus* spp.) together are the cause of 5 to 25 percent of shunt-related infections.[464] *Pseudomonas* spp. and *Acinetobacter* spp. are reported as well, but less frequently. Shunt-related infections caused by gram-negative bacteria occur more commonly in patients with myelomeningocele and those in whom the distal part of the ventriculoperitoneal shunt is inserted into the peritoneal cavity via a percutaneous trocar (i.e., with an inadvertently perforated intestinal tract). Many other etiologic agents, including fungi[82] (e.g., *Candida*,[31,158] *Histoplasma*,[429] *Cryptococcus*,[216] *Torulopsis*[523]), *Pasteurella multocida*,[272] *Neisseria* spp.,[211,470] *S. marcescens*,[63] *Listeria monocytogenes*,[276] nontuberculous mycobacteria,[78] and others, have been reported less commonly as causing shunt-related infections. With the increase in the number of patients who are immunocompromised for various reasons (e.g., neutropenia, chronic intravenous catheters, prolonged administration of broad-spectrum antibiotics, and hyperalimentation), the incidence of these rare infections will increase. Bacteria that traditionally cause meningitis, such as *H. influenzae*,[440,516] *S. pneumoniae*,[354,441,517] and *Neisseria meningitidis*,[273] were reported as causing shunt-related infections. Whether these cases were isolated shunt-related infections or extension of meningitis into the ventricular system (i.e., ventriculitis) is not clear. Therefore, if such bacteria are isolated from a suspected shunt and the patient has a communicating hydrocephalus, lumbar puncture should be performed to rule out meningitis. Of interest, most children with *H. influenzae* or *S. pneumoniae* infections recovered with only antibiotic therapy and without shunt removal.[440]

Pathogenesis

Several observations suggest that most CNS shunt–related infections are caused by inoculation of the organism during surgery or bacterial colonization during the early phase of wound healing.[483] Contamination of the device by ward personnel during manipulation also was suggested.[380,522] These observations include the facts that common skin flora (e.g., coagulase-negative staphylococci and *S. aureus*) are the pathogens most frequently encountered, most of the infections occur within the first few weeks after surgery, and irrigation of the system is a risk factor for the development of infection. Another common mechanism (occurring with gram-negative bacterial infections) is retrograde progression of bacteria from the gastrointestinal tract (i.e., bowel perforation)[206,407] or from the urinary tract (in the case of a ventriculoureteral shunt).[156] Other mechanisms by which shunts become infected include (1) hematogenous infection in which a distant site of infection produces bacteremia leading to a shunt infection (this type of infection occurs quite rarely and in most cases represents meningitis with secondary infection of the shunt, such as *S. pneumoniae* or *N. meningitidis* CNS infection in patients with a shunt) and (2) wound or skin infection (e.g., cellulitis or decubitus ulcer), with direct extension from the infection site to the shunt.

The predominant role of coagulase-negative staphylococci and *S. aureus* in CNS shunt–related infection is the result of their being the major constituents of normal cutaneous flora, especially in young children,[279,433] and

their having the ability to adhere directly to the shunt (e.g., *S. epidermidis*) or to host proteins covering the shunt (e.g., *S. aureus*). In addition, coagulase-negative staphylococci (and some *S. aureus* strains) produce large amounts of extracellular slime (i.e., biofilm) that completely covers the organism.[62] More than 60 percent of staphylococci isolated from infected shunts produce biofilm.[113,133,177] The biofilm of *S. epidermidis* is a mixture of teichoic acid and protein. Production of biofilm also was reported in corynebacterial infection, which may explain the increasing importance of this bacterium in CNS shunt–related infections.[36] The biofilm facilitates attachment of these organisms to the surface of the shunt and protects the bacteria from the host's immune defenses (i.e., reduces phagocytosis). Once the organisms are attached to the shunt material, they are extremely difficult to remove except by completely replacing the shunt. In addition, penetration of antibiotic into the biofilm is variable, and the biofilm antagonizes the antimicrobial activity of some antibiotics (e.g., vancomycin).[118,137] The importance of production of biofilm for the establishment of shunt-related infection caused by coagulase-negative staphylococci was shown by Younger and colleagues,[553] who found that 88 percent of the coagulase-negative staphylococci strains isolated from true shunt-related infections produced slime. Moreover, infections caused by nonadherent organisms were significantly more likely to be cured by antibiotics alone (without removal of the colonized shunt) than were infections caused by adherent organisms. Similarly, Diaz-Mitoma and coworkers[113] found that both obstruction of ventriculoperitoneal shunts and failure to cure the infection with antibiotics alone occurred more frequently when infectious episodes were caused by biofilm-producing coagulase-negative staphylococci. Therefore, complete removal of the shunt should be considered in patients with coagulase-negative staphylococci or *S. aureus* infection because biofilm-producing organisms may not be treated effectively when the shunt is in situ.

S. aureus infection is established primarily by the production of adhesin proteins. The most important proteins are fibronectin-binding (finb A and finb B) and fibrinogen-binding (Clf A and Clf B) proteins.[144] The ability to bind to fibronectin is very common in isolated strains of *S. aureus*, and its efficiency depends on the amount of finb A and finb B expressed on the cell surface of the individual isolate. The two fibrinogen-binding proteins attach to different parts of the host ligand, which suggests that they are acting synergistically or allow the bacteria to adhere to the ligand even during unfavorable conditions (e.g., antibodies against one of them).

The immature humoral immune system of young infants is not likely to explain the increased incidence of shunt-related infections in patients younger than 6 months old because these infants mount antistaphylococcal antibody responses that are comparable to those of older children.[389] Although levels of immunoglobulins and complement proteins are lower in this young group, levels of these proteins normally are very low in the CSF of older individuals (CSF levels of IgG and IgA are between 0.25% and 0.5% of those in serum). In addition, the types of bacteria causing CNS shunt–related infections are not associated commonly with humoral immunodeficiency states, thus suggesting that humoral protection is less important in CNS shunt–related infections. Little is known about the possible role of reduced tissue immunity in these infections.

The foreign body nature of the shunt apparatus plays an important role in the local host defense defect.[55] Electron-microscopic findings demonstrate irregularities in catheters that allow microorganisms to be buried in the catheter. In addition, the function of neutrophils is suboptimal because phagocytic and bactericidal activities are reduced as a result of the loss of lysosomal contents. Therefore, even when pathogens are phagocytized, they may not be killed and are protected from antibiotics that do not penetrate the cell membrane.

Other mechanisms that may contribute to shunt-related infections include (1) abnormal CSF flow (i.e., not being absorbed by the venous sinuses, thought to be important for prevention of infection in the CNS) and (2) interruption of the blood-brain barrier by the shunt catheter, with the creation of a direct tract between the subcutaneous tissues and the ventricles resulting in significant compromise in host defenses.[522]

Clinical Manifestations

The initial signs and symptoms of most patients with shunt-related infections are nonspecific and include mild to moderate fever, malaise, irritability, nausea, vomiting, vague abdominal pain, and headache. With such nonspecific findings, the physician must be careful to differentiate between the possibility of a shunt-related infection and an intercurrent viral or bacterial infection of the upper respiratory, urinary, or gastrointestinal tract. Examination of the CSF (from a shunt tap) may be of help (see the discussion of diagnosis). Only a minority of patients have the classic signs and symptoms of CNS inflammation, such as a stiff neck, bulging fontanelle, change in mental status, cranial nerve palsy, or papilledema. In some patients the shunt tract may be infected, with evidence of cellulitis, dehiscence, or both of the surgical wounds. Tenderness, edema, or erythema along the tract itself may be the only sign. Patients with known seizures (e.g., epilepsy) frequently develop seizures with malfunctioning shunt (inducing infection).[251]

The type of shunt affects the nature of the infection. For example, ventriculoperitoneal shunt–related infections may cause symptoms and signs confined to the abdominal cavity, such as abdominal pain, tenderness (with or without guarding), intestinal obstruction,[403] or spontaneous bacterial peritonitis.[157,330] Rarely, a distal shunt-related infection will be manifested as frank ascites as a result of CSF malabsorption.[262] A relatively common complication of ventriculoperitoneal shunts is an inflammatory peritoneal exudate that may lead to CSF loculation and the subsequent formation of a peritoneal pseudocyst.[15,404] These pseudocysts often are palpable and can be visualized by ultrasonography or CT. Bacteria are isolated in a third of cases, suggesting that infection may play a role in the pathogenesis of pseudocysts. In most cases, however, a high index of suspicion is required because the initial symptoms frequently are abdominal,

with or without food intolerance and with no other signs of shunt malfunction.

A unique complication of patients with ventriculoatrial shunts is the development of immune complex disease such as shunt nephritis (a form of acute glomerulonephritis), arthritis, or rash.[414] In most of these cases, the infecting organism is *S. epidermidis*, but other bacteria such as *Corynebacterium* can cause this complication.[54] In the case of shunt nephritis, the patient has fever, edema, malaise, hepatosplenomegaly, hypocomplementemia, anemia, azotemia, hematuria, and proteinuria.[103] Pathologic findings consist of mesangial hypercellularity and granular deposits of immunoglobulins and complement along the glomerular membrane. Rarely, arthritis may be the initial symptom because it may develop by the same immunologic mechanisms that cause nephritis.[274]

Diagnosis

Although shunt-related infections are not common occurrences, the nonspecific signs and symptoms and the insidious onset in many cases render establishing a diagnosis very difficult. Therefore, any patient with a CNS shunt and fever without an obvious source should be suspected of having a shunt-related infection, especially if the symptoms continue for longer than a week. A higher index of suspicion for shunt-related infection is needed in young patients, in whom fever develops within 3 to 6 months after placement of the shunt. The only definitive diagnostic test is direct observation and culture of CSF. Tapping the shunt or sampling fluid in direct contact with the shunt should be performed if no signs or symptoms of increased intracranial pressure are noted. CT of the head is recommended before the tap is done if such symptoms exist. The shunt tap should be performed with utmost attention given to sterile technique. The tap should be done by a neurosurgeon or physician who is familiar with the technique and the underlying hardware.

When percutaneous needle aspiration is performed, the area around the shunt reservoir should be scrubbed with antiseptic soap and the surrounding hair shaved (2 inches in each direction). The scalp area should be prepared by repeated application (at least three times) of povidone-iodine solution followed by alcohol. A 21- or 23-gauge butterfly needle is placed into the reservoir (or valve if no reservoir is present). Measurement of opening pressure can help diagnose a distal malfunction (i.e., increased pressure) or proximal shunt obstruction (i.e., less than expected pressure). CSF sample aliquots then should be allowed to drip into sterile vials. Gentle aspiration of CSF sometimes is performed if no fluid returns spontaneously. If only a few drops of CSF can be obtained, the more important tests, Gram stain and culture, should be performed first. Culturing the shunt wound, blood, or CSF obtained by lumbar puncture (which usually is not communicating with the ventricular fluid) often is unrevealing, misleading, or both. Although bacteremia frequently is present in patients with ventriculoatrial shunts and may help diagnose the etiologic agent, blood cultures generally are negative in patients with all other shunts (e.g., ventriculoperitoneal or pleural shunts). In addition, coagulase-negative staphylococci are the most common contaminants of blood cultures, and, therefore, interpreting a positive blood culture in these patients would be difficult.

CSF should be tested for glucose concentration, differential cell count, Gram stain, and culture. Protein concentration is requested often but is of very limited help in evaluating the presence or absence of an infection because high protein levels are found in many patients with shunt malfunction and no infection. In contrast, normal protein levels have been reported in many patients with shunt-related infections. A low glucose level suggests an infection, but one should confirm that the CSF sample was not diluted before the test was performed. Some physicians use saline to get a better flow of CSF (because of an occluded tube), which may affect the biochemical results. Of importance is to note that in many cases of shunt-related infection, the glucose level is within the normal range. Usually, pleocytosis with a predominance of PMNs is indicative of a shunt-related infection. A count of 100 cells/μL or more is highly suggestive of infection.[268,277,319] A WBC count greater than 100 cells/μL with more than 10 percent PMN cells in febrile patients is 82 percent sensitive and 99 percent specific for shunt infection, with a positive predictive value of 93 percent.[319] In contrast, if the PMNs are less than 10 percent, the negative predictive value (i.e., no infection) is 95 percent. A recent review suggests that infection with gram-negative bacteria resulted in a higher initial and peak WBC count, with a greater percentage of PMNs than gram-positive bacteria.[151] In contrast, *P. acnes* was associated with the lowest WBC and PMN percentage. The possibility that these conclusions were affected by a higher percentage of shunt colonization or culture contamination with gram-positive bacteria and *Propionibacterium* spp. should be kept in mind when interpreting these results. Although in some cases the finding of a positive CSF culture is interpreted as a shunt-related infection despite a normal WBC count (<10 WBCs/mm^3), the absence of clinical symptoms (e.g., fever) in many of these patients suggests that the positive culture probably represents colonization or contamination. Other cells, such as mononuclear cells[257,464] or eosinophils[319,532] may predominate during an infection. If eosinophilia is the predominant cellular response, an allergy to the shunt (e.g., silicone[225]) or the materials used for sterilization (e.g., ethylene oxide[386]) or use of an antibiotic-impregnated catheter[494] or intraventricular administration of antibiotics (e.g., gentamicin[329] and vancomycin[171]) should be considered. Other conditions should also increase the eosinophil count in the CSF.[440] It is important to note that eosinophilia (without these causes, including infection) is relatively common (but transient) in children with CNS shunt.[150,188] Leakage of CSF under the skin or blood in the CSF are two possible reasons for this phenomenon.

Interpretation of the WBC count should be done cautiously if the red blood cell count is high because the increased number of WBCs can be the result of blood spilling into the CSF without any infection or be part of the inflammatory response to the presence of blood (i.e., chemical ventriculitis).[381] A positive Gram stain with an increased CSF WBC count, reduced glucose level, or both is helpful in making the diagnosis of a shunt-related infection. A negative Gram stain result

does not exclude an infection, and one should wait for the results of culture. Ventricular fluid always should be cultured anaerobically as well as aerobically. Although most bacteria causing shunt-related infections grow within 48 to 78 hours, cultures should be held for 7 days (if still negative) for fastidious organisms such as *Propionibacterium*.[25] The possibility of contamination or colonization of the shunt without infection should be considered when the culture is positive but other CSF parameters are normal. If such a scenario occurs and bacteria are growing only from one sample (e.g., a shunt tap) and not from follow-up cultures (i.e., from extraventricular drainage), a shorter course of therapy (see later discussion) may be sufficient.

Blood cultures, a peripheral complete blood count (CBC), and ultrasound of the abdomen (for ventriculoperitoneal shunts) are of limited value. For example, although 90 percent of patients with ventriculoatrial shunt–related infection will have a positive blood culture, fewer than 10 percent of patients with other shunt-related infections will have a positive culture. In addition, in more than a third of patients with shunt-related infections, no elevation in the peripheral WBC count was found. Some investigators suggest that blood but not CSF CRP levels may be helpful in establishing the diagnosis of shunt-related infection when other concurrent infections (e.g., sinusitis, pneumonia) were excluded.[268,425] One suggestion is that if the CRP level is less than 7 mg/L, the shunt should not be removed because no infection is present. More data are needed to verify this observation. In patients with a ventriculoatrial shunt–related infection, measurement of serum antistaphylococcal antibodies or the C3 and C4 components of the complement cascade may aid in establishing the diagnosis.[37,414] The triad of fever, abnormal CSF WBC count, and greater than 5 percent eosinophilia is highly predictive of a shunt-related infection.[319]

Treatment

A variety of medical and surgical approaches to treatment of an infected shunt have been suggested.[532] Regimens include (1) the use of antibiotics alone (systemically, with or without intraventricular administration) without replacement of the shunt; (2) removal of the infected shunt followed by immediate insertion of a new shunt and the administration of systemic or intraventricular antibiotics or both[344]; (3) removal of the infected shunt and insertion of an extraventricular device (EVD) to monitor the patient's response to the accompanying antibiotic therapy, with a new shunt inserted only when the ventricular system is sterilized; (4) removal of the infected shunt followed by a stereotactic third ventriculostomy and administration of antibiotics; and (5) externalization of only the distal (e.g., peritoneal) catheter, along with the administration of systemic or intraventricular antibiotics or both.

The use of antibiotics alone without surgery was justified by the need to maintain CSF drainage and avoid costly operations and lengthy duration of hospital stay. The low success rate of this approach (33%) and the higher mortality rate associated with it suggest that it should not be used (Table 74-3). Of interest, the failure rate was much higher with infections caused by slime-producing organisms than with infections caused by non–slime-producing bacteria.[113] Only in shunted patients

with purulent meningitis caused by *S. pneumoniae*, *N. meningitidis*, or *H. influenzae* did the administration of systemic antibiotics alone without removal of the shunt seem to be an acceptable option.[273,359]

Combining immediate replacement of the infected shunt with a new shunt and antibiotic therapy has a higher rate of success (70%, see Table 74-3) than does the use of antibiotics alone. Nonetheless, it is less effective than removal of the infected shunt accompanied by insertion of an EVD and administration of antibiotic therapy (88% success rate, see Table 74-3). A decision analysis of 17 studies reached the same conclusion and suggested that "this treatment option has the highest cure rate and the lowest failure and mortality rates."[424] In addition, lack of the ability to monitor when the ventricular fluid is sterilized results in a longer period of systemic antibiotic therapy (e.g., 4 to 8 weeks), which may lead to an increase in iatrogenic infections and cost. Some surgeons suggest removing the shunt and delaying replacement (i.e., a few days after removal to allow sterilization of the shunt's tract), but this approach is associated with increased morbidity.[143,524]

For infection that involves only the distal part of the shunt (e.g., pseudocyst, appendicitis,[370] erythema or swelling along the shunt tract, or surgical wound infection), externalization of only the distal end of the shunt along with the administration of antibiotic therapy is recommended by some neurosurgeons. Potential advantages of this technique include (1) diversion of CSF from an infected area to avoid ascending infection, (2) maintenance of CSF flow to prevent increased intracranial pressure (ICP), (3) the ability to perform frequent CSF sampling, and (4) the capability of monitoring therapy. The disadvantage is that early infection or colonization of the proximal portion of the shunt may be obscured by the antibiotic treatment and become active after discontinuation of therapy and reinsertion of the distal part. In patients with *P. acne*–related distal shunt infection, catheter removal without (or very short) antibiotic treatment is sufficient.[25]

Internal shunting by a third ventriculostomy with avoidance of a prosthetic device during the infected CSF shunt removal was investigated as another option to reduce reinfection. Although this procedure was shown to be effective in managing patients with refractory shunt-related infections who have a noncommunicating hydrocephalus, patent subarachnoid space, and adequate CSF absorption, the preventive effect for reinfection was marginal.[143,313,346,437,441] Yet, it seems that the reinserted ventriculoperitoneal shunts after a third ventriculostomy have a better longevity than those inserted without this procedure.[437] Shunt independence for extended periods was documented in patients without myelomeningocele. The success rate is lower in those with myelomeningocele or hemorrhage or after meningitis. Disadvantages of this technique include increased morbidity (e.g., hypothalamic injury and subarachnoid hemorrhage), technical difficulty in younger children, and, if the stereotactic technique is used, cost and availability of the necessary equipment.[130]

The most effective treatment of shunt-related infections is to remove the entire infected shunt and insert an EVD to control ICP and monitor the infection (i.e., provide CSF access). After antibiotic therapy has been successful, a new shunt is placed. With this approach, treatment success is very high (see Table 74-3), with more rapid clearance of the infection and a shorter duration of therapy. The choice of intravenous antibiotic depends on local patterns of antimicrobial susceptibility and the ability of the antibiotic to penetrate the blood-brain barrier. With the increasing rate of methicillin-resistant staphylococci, vancomycin should be used as initial therapy while awaiting bacteriologic identification and the results of antibiotic sensitivity testing. Effort should be made to discontinue vancomycin as soon as the infecting bacteria are found to be sensitive to the semisynthetic penicillins so that the chance of the bacteria becoming resistant to vancomycin is reduced. In addition, even if in vitro data suggest that the bacteria are highly sensitive to the first-generation cephalosporins (e.g., cephalothin, cefazolin, and cephapirin), they should not be used because they penetrate the blood-brain barrier poorly. Linezolid has been used successfully in cases of shunt infection.[52,75,350,512,550] This drug has a good CSF penetration, with concentrations above the minimal inhibitory concentration (MIC) of most gram-positive bacteria, including MRSA.[38,552]

It is also effective against bacteria living in biofilms. The limited data available suggest that linezolid should be considered cautiously when vancomycin fails or cannot be given.

To achieve more consistent and efficient eradication of bacteria, the CSF drug level should be at least 10 times higher than the MIC of the pathogen. Therefore, the dosage of antibiotic or antibiotics and the dosing interval should be maximized (i.e., "meningeal schedule"). If the selected antibiotic does not clear the infection within 2 to 3 days and no improvement occurs in CSF biochemical and WBC parameters (i.e., seemingly no control of the infection), measurement of the bactericidal titer of ventricular fluid should be considered. To determine bactericidal titer, 1 mL of CSF (if CSF production is >5 mL/hr) at the expected peak antibiotic level (i.e., 2 to 3 hours after the antibiotic is given parenterally) is diluted serially with culture media to produce dilutions of 1:2, 1:4, 1:8, and 1:16. To these dilutions, an equal amount of medium with 10^5 colonies per milliliter of the offending bacteria is added (the final CSF dilution is 1:4, 1:8, 1:16, and 1:32). After 24 hours of incubation, the tubes are observed for turbidity, which reflects the growth of bacteria. If no turbidity is seen in the 1:8 and 1:16 or higher dilution tubes, the CSF level of the antibiotic probably is sufficient, and continued growth of bacteria from CSF may be caused by colonization of the EVD or contamination. On the other hand, if turbidity is noted in the tube with less than a 1:8 dilution (i.e., a 1:4 dilution), the CSF level of antibiotic may not be sufficient to combat the infection and the addition of another antibiotic or change to a different antibiotic is warranted.

In vitro synergy studies can help determine the best drug combination. Rifampin should be considered as one of the drugs in the combination for gram-positive bacteria for three reasons. First, most staphylococci are still sensitive to this antibiotic and their MIC usually is 10-fold

lower (i.e., 0.05 μg/mL) than that of other antistaphylococcal drugs (e.g., vancomycin, 0.5 μg/mL). Unfortunately, the use of rifampin alone may be followed rapidly by rifampin-resistant variants because they already are present in small numbers in any staphylococcal population. Second, rifampin penetrates CSF well and easily achieves a greater than 10-fold level over the MIC of most staphylococci. Third, rifampin has demonstrated good bactericidal activity even when staphylococci were embedded in slime. In contrast, staphylococcal slime inhibits the antimicrobial activity of vancomycin.[137]

Selection of the initial antibiotic before culture results are known can be based on the patient's clinical and CSF findings. An algorithm for initial antibiotic therapy before CSF culture results are available is presented in Figure 74-2. This algorithm should not be used for neonates or immunocompromised patients with suspected shunt-related infections because they often have less severe clinical symptoms and CSF response. The decision-making process starts with assessment of the patient's clinical condition. Usually, patients with infection in the CNS are only mildly symptomatic, whereas patients with *S. aureus* or gram-negative bacterial infection often are more seriously ill.

The next step is evaluation of the Gram stain. If the Gram stain result is positive for gram-positive bacteria (e.g., *Staphylococcus* or *Streptococcus*), the drug of choice is vancomycin. If the Gram stain shows gram-negative bacteria, the drug of choice is cefotaxime or ceftriaxone. Treatment with an aminoglycoside is acceptable, but the outcome seems to be less favorable because of poorer penetration into CSF.[363] If the Gram stain result is negative, other CSF parameters (e.g., WBC count and glucose) should be examined. If either is abnormal and the patient is not severely sick, vancomycin alone should be started because the chance of having a gram-negative infection is low.[463]

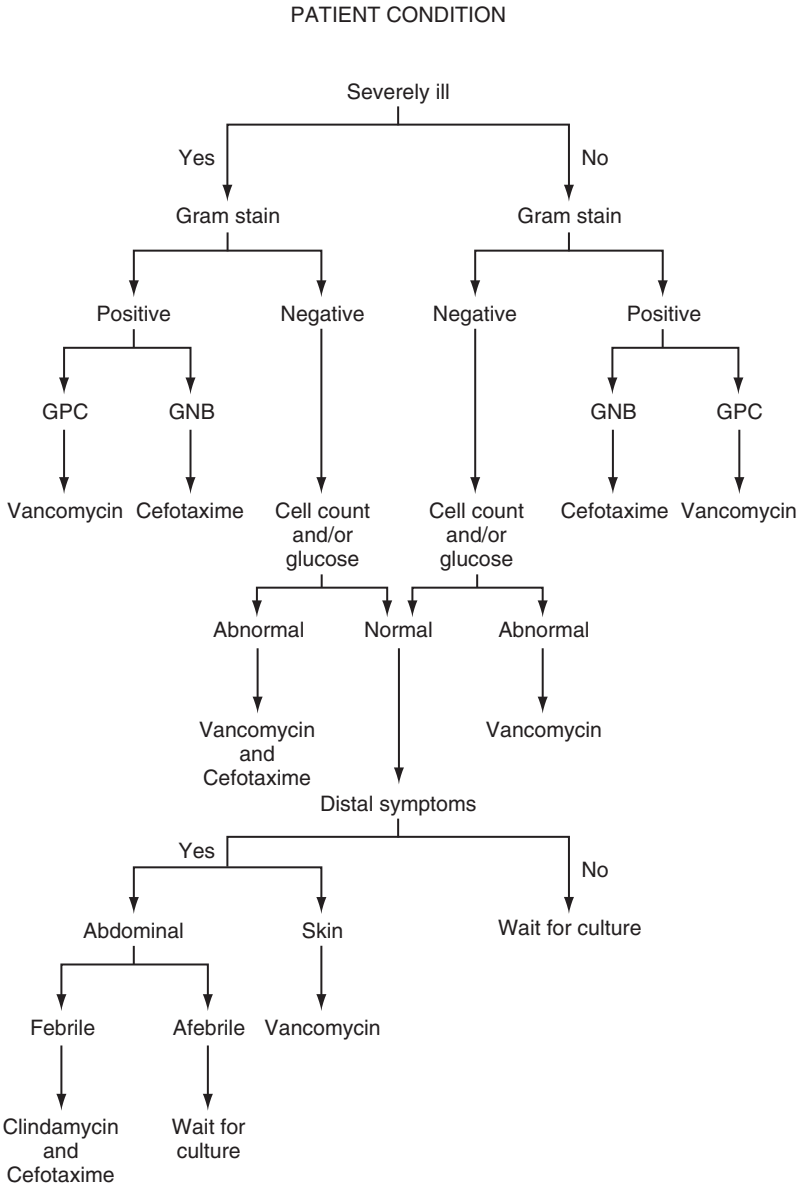

FIGURE 74-2 ■ Algorithm for selection of antibiotic therapy before culture results are known. *GNB,* Gram-negative bacillus; *GPC,* gram-positive coccus.

In contrast, if the patient is more seriously ill, coverage for gram-negative bacteria should be added (e.g., cefotaxime or ceftriaxone). In nontoxic patients with normal CSF parameters and no distal symptoms (e.g., peritonitis or wound or tract infection), antibiotic therapy can be withheld until the results of culture are known. On the other hand, if distal signs or symptoms exist, therapy is tailored according to the site. In patients with skin involvement, vancomycin is the drug of choice, whereas in febrile patients with abdominal symptoms, the combination of cefotaxime (or ceftriaxone) and clindamycin (to cover both gram-positive and anaerobic bacteria) is preferred.

Direct instillation of antibiotics into the ventricular system to increase their levels is suggested by some experts.[555] Such treatment may be considered in patients with persistently positive cultures despite intravenous therapy or multidrug-resistant organisms requiring specific antibiotics with inadequate CSF penetration. Several studies have reported promising results using combination of intravenous and intraventricular therapy.[127,287,479] Unfortunately, the suggested doses for intraventricular treatment have been determined empirically on only a small number of patients, and their pharmacokinetics and pharmacodynamics have not been studied well. This therapy is not without hazard, especially when the recommended doses often are much higher than those found to cause neurotoxicity.[252,448,528] Pleocytosis and eosinophilia also have occurred in patients receiving intraventricular vancomycin[290] or gentamicin.[329] In addition, preservative-containing preparations should be checked for appropriateness for intraventricular instillation. Limited pharmacokinetic data suggest that clearance of the instilled intraventricular antibiotic is sufficiently slow to allow once-daily administration. If possible, the EVD should be closed for 30 to 60 minutes after the drug is administered. If the EVD cannot be closed and the amount of CSF drainage exceeds 7 to 10 mL/hr, the frequency of intraventricular antibiotic instillation should be increased to twice daily.

Antibiotics commonly recommended for intravenous and intraventricular use according to the etiologic agent are shown in Table 74-4. A small study in adults showed that administration of vancomycin 10 mg intraventricularly once daily was safe and achieved levels greater than 5 μg/mL (the recommended CSF trough level needed to achieve cure) for up to 21 hours.[383] Because of the potential toxicity of the empirically recommended intraventricular antibiotic doses and the unpredictability of CSF levels, irrigation of the ventricular system with a known concentration of an antibiotic solution is preferred when systemic antibiotics fail to eradicate the bacteria. To achieve irrigation, two EVDs must be inserted to produce a continuous flow of solution. The concentration of antibiotic in the solution should be equal to the highest safe plasma level when the drug is given intravenously. For example, for treating gram-negative bacteria sensitive to amikacin, amikacin at a dose of 30 to 40 mg/L of saline solution (producing a concentration of 30 to 40 μg/mL) is recommended. Gentamicin 10 to 12 mg/L (using a special intrathecal preparation) is an acceptable alternative when the gentamicin MIC for the bacteria is less than 1 μg/mL. The antibiotic solution is administered through one EVD at a rate of 10 mL/hr, and the second EVD is left open to drain the fluid and to remove debris and pus from the ventricles.

When antibiotic therapy is completed, abnormal CSF findings such as low glucose or mildly elevated protein or cell counts should not delay reshunting. The duration of treatment is empirical and depends on the etiologic agent, the CSF parameters at initial evaluation, and the time to sterilization. In our institution, we found the following schedule to be successful. If CSF parameters are *normal* but culture yields coagulase-negative staphylococci only from the operating room (i.e., the initial sample), therapy should be given for only 3 to 4 days. If subsequent cultures also are positive, therapy should continue until negative cultures have been obtained for 7 days. If CSF parameters are *abnormal* in the operating room and culture is positive *only* from that specimen, therapy should continue for 7 days. If subsequent samples show abnormal CSF findings and positive cultures, therapy should be extended until negative cultures have been obtained for 10 days. This protocol was adopted by the Infectious Diseases Society of America guidelines for the management of CSF shunt infections.

A longer duration of antibiotic therapy is recommended with other bacteria (e.g., *S. aureus*, gram-negative bacteria). If culture is positive *only* on samples from the *operating room* and CSF findings are normal, treatment should be given until negative cultures have been obtained for 7 days. In all other situations, therapy should continue until negative cultures have been achieved for 10 days. Reshunting should take place immediately at the end of treatment. No benefit is found in observing the patient for a time without antibiotics for relapse of the infection.[526]

Complications

Shunt-related infections are associated with increased morbidity and mortality rates. Patients with shunt-related infection have an increase in shunt-related operations, which contributes to the increased morbidity and cost. In addition, these patients have been shown to have an increase in mortality rates in contrast to patients without shunt-related infection.[448] Even when the original infection is treated successfully, secondary infection (or contamination) of the EVD occurs in 5 to 10 percent of cases. To minimize the risk for development of a secondary infection, a sterile closed-drainage system should be maintained carefully. Only trained personnel should be allowed to drain CSF samples from the system, and injections into the system should be avoided. Continuous external drainage of CSF also causes loss of electrolytes and fluid. Therefore, routine assessment of serum electrolytes once or twice weekly is recommended, and the total daily amount of drained CSF should be replaced. Recurrent shunt-related infection after completion of treatment is common, with two thirds of such infections being caused by the same organism.[243] Unusual complications of ventricular shunt infections include brain abscess and subdural empyema.[132,519]

TABLE 74-4 **Recommended Intravenous and Intraventricular Antibiotic Therapy for Shunt Infection According to Etiologic Agent**

Etiologic Agent	Antibiotic	Intravenous Dose (mg/kg/day)	Intraventricular Dose (mg/day, 1 Dose)

*In patients allergic to penicillin, use vancomycin.
†If cerebrospinal fluid levels are not sufficient and the bacteria are sensitive to rifampin, add rifampin, 20 mg/kg/day divided every 12 hours.
‡See doses (for the specific aminoglycoside) for treatment of *E. coli* below.
§The addition of a broad-spectrum penicillin (e.g., piperacillin or ticarcillin, 300 to 400 mg/kg/day divided every 6 hours) may add to the bactericidal activity.
¶If ventricular fluid remains positive after 5 to 7 days of therapy with amphotericin, add flucytosine (150 mg/kg/day divided every 6 hr).
NA, Not available.

Prognosis

Complete removal of the shunt system results in better prognosis.[444] Long-term morbidity occurring after a shunt-related infection includes seizures, psychomotor retardation, and cognitive deficiency. The intelligence quotient (IQ) scores of children with myelomeningocele who had a shunt-related infection were found to be significantly lower (mean IQ, 72) than the scores of children with shunts but no infection (mean IQ, 95).[324] A trend was observed in which younger children with shunt-related infections had a lower IQ than older children with shunt-related infections, especially if the infection was caused by gram-negative bacteria. In addition, shunt-related infection adversely affected school performance.[516] With appropriate combined medical and surgical therapy, the mortality rate from shunt-related infection is low, but any episode of shunt-related infection appears to increase the probability of another episode developing.

Prevention

Standardized care protocols have been shown to reduce infections.[207,244,385,456] Preventive measures to reduce the incidence of shunt-related infection include attention to preoperative and intraoperative technique and the prophylactic use of antibiotics. Bactericidal shampoos (e.g., chlorhexidine) should be used to reduce the bacterial density of the scalp before surgery is performed. Shaving the scalp seems to be a risk factor, so shaveless surgery should be considered.[210] During the operation, only essential personnel should be present, and the skin should be cleaned with a fat solvent, followed by solutions that reduce the number of bacteria (elemental tincture of iodine, 20 ppm, is preferred over 10% povidone-iodine, which contains <1 ppm free iodine)[83] or their ability to adhere to the shunt (bacitracin A).[170] Careful attention should be paid to surgical technique, with contact between the shunt and the skin avoided. A detailed preoperative protocol developed by the Hydrocephalus Clinical Research Network (HCRN) has reduced the infection rate from 8.8 to 5.7 percent.[244] Other investigators were able to reduce the infection rate by using measures similar to those suggested by the HCRN.[84] A single-center study showed that infection rate was reduced from 21 to 4.3 percent when nonantimicrobial impregnated sutures versus impregnated sutures were used, respectively[445] and other studies suggested that use of an antibiotic-impregnated shunt system significantly reduces the incidence of shunt infections in contrast to the use of a standard shunt.[169,367,371,430,431] Yet, no significant reduction in the overall shunt-related infection rate was observed in other studies.[187,233] In addition, the antibiotic-impregnated catheter may increase the rate of bacteria resistant to its antibiotic components.[111] Large prospective, randomized studies are needed to evaluate the real contribution of an antibiotic-impregnated shunt to the reduction in infection rate.

Multiple studies have examined the effect of prophylactic antibiotics for the shunt insertion procedure on reducing the infection rate.[61,269,396,397] Major variations in study design and the number of patients in each study preclude arriving at definitive conclusions. Previous meta-analysis of well-designed studies suggests that the use of prophylactic antibiotics is associated with a significant reduction in the incidence of infections *if* the baseline rate of shunt-related infections is greater than 5 percent.[180] If the infection rate is lower than 5 percent, prophylactic antibiotics are *not* recommended. A recent meta-analysis of 2134 patients (in 17 trials) found a statistically significant benefit for either systemic antibiotic prophylaxis (15 studies) or antibiotic-impregnated catheters (2 studies) in reducing the incidence of shunt-related infections, and some experts suggested to add intraventricular antibiotic administration (e.g., gentamicin or vancomycin) during the procedure.[393,396] The choice of antibiotics should be based on the local antibiotic sensitivity pattern of the pathogens commonly causing shunt-related infections in that area. Although many experts recommend giving the first dose 30 to 60 minutes before skin incision, prophylaxis should be considered to start 8 to 12 hours before surgery to allow higher levels of drug to accumulate in skin tissue than would do so if treatment were given just before the operation. The duration of prophylaxis should not exceed 24 to 36 hours. Further studies are needed to identify factors important in the development of shunt-related infections so that better techniques can be developed to further reduce or even eliminate this devastating complication of CNS shunting.

INTRACRANIAL PRESSURE MONITORS

Monitoring of ICP has become an important part of the evaluation, treatment, and management of children with a variety of intracranial pathologic processes,[291] including congenital anomalies (e.g., cranial or craniofacial dysostosis), metabolic diseases (e.g., Reye syndrome), trauma, intraventricular or subarachnoid hemorrhage, intracranial infections (e.g., encephalitis), and other ischemic or hypoxic insults.[365] Several studies have demonstrated the therapeutic and prognostic benefit of monitoring ICP in children with high ICP[145,224,280,484]; nonetheless, this procedure is not without complications such as hematoma, bleeding, leakage of CSF, and infection. Infections for which monitoring of ICP is used include ventriculitis, meningitis, brain abscess, subdural empyema, skin infection, and cranial bone infections.[253,290,541]

Several methods are available for monitoring ICP. Intraventricular placement of a catheter with the distal end connected to a pressure transducer is the method used most frequently because of its accuracy and ease of calibration. This procedure also allows drainage of CSF for biochemical or dynamic testing. Disadvantages of ventriculostomy are penetration of the meninges and brain, technical difficulties if the ventricles are small, and greater risk for the development of infection. Other methods used to monitor ICP include a subdural bolt or catheter (only the meninges are penetrated, but the brain remains intact), an epidural transducer (the dura remains intact), and a continuous intraparenchymal monitor (i.e., a fiberoptic cable is inserted through the dura into the brain parenchyma, not intraventricularly). Although both the epidural transducer and the intraparenchymal monitor have fewer complications (e.g., infection) than the intraventricular devices, they are prone to inaccuracy, which limits their use. Selection of the appropriate ICP-monitoring method depends on the patient's condition and the risk associated with the procedure.[298]

Epidemiology

Assessing the true infection rate of ICP monitoring devices is very difficult, mainly because the methods used to define infection (i.e., inclusion and exclusion criteria), the indication for ICP placement, and antibiotic use vary widely among reported studies. The incidence of infection ranged from less than 1 percent to 45 percent, with an average infection rate of 9.5 percent.[247,289] A much higher rate of infection was reported in patients who had devices that penetrated the meninges[202] than in those who had parenchymal monitors.[390]

TABLE 74-5 **Risk Factors for Infection of Devices for Monitoring Intracranial Pressure**

Intraventricular hemorrhage
Subarachnoid hemorrhage
Neurosurgical procedure or operation
Perforation of the dura
Duration of catheterization
Cerebrospinal fluid leak from fracture or intracranial pressure site
Open head trauma or fracture
Intracranial pressure >20 mm Hg
Blockage
Disconnections
Frequent manipulation of the intracranial pressure device Dressing changes or irrigation Sample collection Device component changes

Multiple factors were suggested as increasing the risk for development of ICP device–related infection (Table 74-5).[192] Patients with intracerebral hemorrhage usually do not have a higher risk for acquiring infection than those without such hemorrhage. In contrast, if the bleeding is intraventricular, the incidence of infection increases dramatically. The rate of infection also is higher in patients with open head trauma than in those with closed head trauma or intracranial malignancy.[212] Neurosurgical operations contributed significantly to the risk for acquiring infection,[241,373] and the same was noted if ICP was greater than 20 mm Hg.

Interruption of the monitoring system's integrity (e.g., CSF leak, number of times that the system was open, malfunction, and irrigation) was identified by several investigators as increasing patient risk for acquiring infection.[81,197,296] The effect of the duration of monitoring on the risk for infection is controversial, especially in patients with ventriculostomy catheters. Although several studies found a correlation between the length of time that the monitoring device was in place and the infection rate,[247,289] some investigators found no relationship with the duration of monitoring.* The different conclusions probably were the result of differences in the populations studied, the types of devices used to measure ICP, the definitions of infection, and analyses of the data. A critical review of the literature evaluating 23 major studies found a correlation between the duration of ICP monitoring and the rate of infections.[289]

The need to replace the device at a certain time has been challenged. Analysis of the outcome in 584 patients (receiving 712 ventriculostomy catheters) who had 61 infections showed a steady increase in the daily incidence of infection that peaked at day 10 with an average time to onset of infection 6.8 days.[202] Only one infection occurred after day 10. These data suggest that the majority of infections occurred early after the ICP insertion and, therefore, ICP monitoring devices should be removed as quickly as possible, but if "prolonged monitoring is required, there appears to be no benefit from or need for catheter exchange."[202]

*References 21, 81, 197, 286, 420, 421, 492.

Etiology

In general, the microorganisms that cause infections related to ICP monitoring devices are the same as those causing CNS shunt–related infections (see Table 74-2). The major difference is that gram-negative bacteria are isolated more often in ICP monitor–related infection than in CNS shunt–related infections.[286,296,418] The more common bacteria include *Enterobacter* spp., *Klebsiella* spp., *S. marcescens*, and *Acinetobacter* spp. These bacteria are found in water and cause widespread colonization of hospitalized patients. Colonization of the respiratory tract is an especially common occurrence in patients in the intensive care unit and in those with serious underlying disease. Thus, these organisms are occurring increasingly frequently in ICP monitor–related infections. Few infections are caused by *Corynebacterium*, *Propionibacterium*, and fungi.[179,420]

Clinical Manifestations

ICP monitor–related infections often occur in patients with an altered sensorium; therefore, the signs and symptoms of meningeal irritation usually are not present. The clinical diagnosis is complicated further by the fact that these patients frequently are critically ill and their signs and symptoms are caused by the underlying condition and are not a result of the ICP monitor–related infection. In addition, they may be receiving multiple antibiotics for other sources of infection (e.g., pneumonia, bacteremia, or urinary tract infection), both nosocomial and non-nosocomial. Although fever is the most frequent indication of infection, the presence of infections or inflammatory processes at other body sites causes the predictive value of fever to be low. Therefore, providing close follow-up, having a high index of suspicion, and obtaining frequent cultures of CSF when available (e.g., ventriculostomy device) are recommended.

Diagnosis

The predictive value of the peripheral WBC count and differential count are very low, and the diagnostic specificity of the CSF parameters is questionable.[383,418] CSF biochemistry (i.e., protein and glucose) has a very low predictive value. Although a low glucose level may be of help in establishing the diagnosis, a normal level does not exclude the possibility of an infection. Calculation of the ratio of leukocytes to erythrocytes in CSF versus their ratio in peripheral blood was suggested as a potential diagnostic tool for early infection, but it was not validated in a subsequent study.[383,418] Most patients with ICP monitor–related infection will have an increased CSF WBC count with a predominance of PMNs, but in cases with low growth of bacteria, no elevation in CSF WBC counts (<10/mm^3) was reported. Most of these cases were caused by coagulation-negative staphylococci. In such cases, if no other indicators of infection (e.g., clinical

symptoms or low glucose) are present, the possibility that the positive cultures represent colonization or contamination should be considered before treatment is initiated.

Treatment and Prophylaxis

Only a few control trials have evaluated treatment strategies for ICP infection; therefore, the same principles used for the management of CNS shunt–related infections can be applied to infections associated with ICP monitoring devices. The use of antibiotics alone without removal of the device may be adequate for the treatment of infections associated with devices placed in the subdural or epidural space, unless an abscess or empyema has formed. In the case of ventriculostomy, the infected device should be removed and appropriate antibiotic therapy instituted. Because gram-negative bacteria are also causing ICP device–related infections, initial antibiotic therapy should include both vancomycin and cefotaxime or ceftazidime if the Gram stain is negative. When the etiologic agent is identified, the specific antibiotic or antibiotics can be chosen from those listed in Table 74-4. The optimal treatment for fungal infections is unknown. Clinical experience with amphotericin B suggests that it is effective despite the fact that it achieves low levels in the CSF. Because fluconazole and voriconazole are known to achieve the best CSF levels, they should be considered as the first drugs of choice.[245] The duration of therapy depends on the etiologic agent and the CSF parameters. In patients with positive CSF culture but minimal CSF pleocytosis, if the CSF culture becomes negative immediately after removal of the catheter, therapy should be given for only 3 or 4 days because the cultures before removal of the catheter reflect colonization and not infection. If subsequent cultures are positive, therapy should continue for 10 days of negative cultures.

Although removal of the ICP monitor (if longer than 5 days) and reinsertion at an alternative site was recommended as a prophylactic approach to reduce the infection rate, this practice is controversial, and several studies showed that routine changes of the ICP monitor did not reduce the risk for development of infection.[289,543]

Many physicians use prophylactic antibiotics for the duration of ICP monitoring in the hope of preventing infection. Unfortunately, the studies that have evaluated the utility of antimicrobial agents in preventing such infections reported contradictory results.[400] A decreased rate of ICP monitor infection was reported in patients who received prophylaxis for the duration of the ICP monitoring.[387] Yet, other studies showed no benefit of either preprocedural only or combined with prolonged antibiotic therapy (until the device was removed).[9,73] In contrast, Poon and colleagues[387] reported that prolonged use of antibiotics reduced the infection rate but had an increase in MRSA and *Candida* infections. In addition, broad-spectrum antibiotic prophylaxis was associated with shifting to resistant gram-negative pathogens.[312] Observational studies suggested that use of antibiotic-coated devices significantly reduced infection rate in contrast to historical control[178,340] and the same results were seen in a longitudinal study comparing infection rates in patients with and without antibiotic-coated catheter.[186] The investigators observed a rate of 6.7 percent reduced to 1 percent when coated catheters were used and climbing to 7.6 percent when standard catheters were reintroduced. When coated catheters were again reintroduced, the infection rate dropped to 0.9 percent. In contrast, a retrospective analysis of patients who developed ventriculitis after placement of either antibiotic-coated EVD or non–antibiotic-impregnated EVD found no major advantage for the impregnated device.[454] A recent systematic review of all studies evaluating systemic prophylactic antibiotic throughout the duration of the external ventricular drainage or placement of antibiotic-coated devices concluded that there is probably some benefit to using either of them.[455] The varying quality of the reviewed studies (most nonrandomized) suggests that cautious interpretation and further research is needed to confirm these findings. In the meantime, antibiotic-impregnated catheters (with or without systemic antibiotics) should be considered for prophylaxis.

INTRATHECAL PUMP INFUSION DEVICES

The intrathecal pump infusion system currently is used to infuse morphine to treat refractory pain,[356] deliver baclofen (a γ-aminobutyric acid agonist), or treat spasticity of spinal or cerebral origin.[7,24,375] In addition, patients with generalized dystonia also benefited from intrathecal baclofen.[6] More than 50,000 patients are being treated with implanted intrathecal pumps for pain or spasticity. Several pump systems are used. The simpler systems consist of an externalized catheter system similar to the Hickman catheter[118] or a subcutaneous reservoir system similar to an intravascular implanted port. The more sophisticated systems include a programmable pump that usually is implanted in an abdominal subcutaneous pocket and connected via a subcutaneous catheter to the subarachnoid space.[39] An optional sideport in some of these implanted pumps allows aspiration of CSF from the subarachnoid space.

Complications of the intrathecal pump system are relatively rare events[165,506] and include mechanical problems with the catheter, such as breaking, kinking, dislodging, or leaking.[480] Skin necrosis also has been reported.[155,480] Complications (especially wound complications such as CSF fistula, dehiscence, granuloma formation, and infection) occur more frequently in children than in adults, probably because of their decreased muscle and subcutaneous tissue.[9,142,506] The pump itself is very durable and only very rarely causes a mechanical problem. Overdose that may result in coma, respiratory depression, apnea, cardiac conduction abnormalities, hypotension or hypertension, and abnormalities of the pupils was reported as well.[378] Intrathecal baclofen can induce both recurrent and new-onset seizures.[24,256] In addition, acute withdrawal syndrome was reported when treatment was stopped.[442] Infectious complications included suppuration at the exit site,[69,120,201] along the subcutaneous catheter (tunnel infection),[39,69,120,201] or around the pump.[39,69,80]

Furthermore, more severe infections such as epidural abscess and meningitis also were reported.*

Epidemiology

The infection rate of intrathecal pump infusion devices ranges from 1.2 to 6.1 percent.[20,56] Of note, in general the infection rate was lower in studies that included a larger number of patients. Systemic review of the literature identified 10 studies with 821 patients in whom 20 catheter-related infections were found—10 superficial (rate of 2.3%) and 10 deep (rate of 1.4%).[20] A more accurate description of the incidence would be the infection rate per 1000 catheter-days, which ranged from 0 to 2.5. The infection rate was higher in patients with an externalized catheter (0.65/1000 catheter-days) than in those who had an implanted system (0.48/1000 catheter-days). A meta-analysis of epidural catheters showed that 1/35 patients having the catheter for an average of 74 days developed epidural abscess.[409] Most of the infections occurred at the exit site, along the catheter, or in the subcutaneous pocket of the pump, but the infection in as many as 16 percent of cases involved the epidural space, the meninges, or both. The incidence of infections can be reduced by using the subfascial pump implementation technique and perioperative antibiotic prophylaxis.[56,339]

Infections occur more often within 2 to 4 weeks after insertion of the catheter, which suggests that the initial surgery to place the intrathecal pump system may be a risk factor. Byers and coworkers[69] found that the only risk factor associated with infection during this surgery was a prolonged duration of the procedure (i.e., >100 minutes). Multiple other factors, such as patient age, underlying diseases, immune deficiency, other concurrent infections (e.g., pneumonia), previous intrathecal catheter, number of pump refills, intraspinal anesthetics, surgeon or anesthesiologist experience with the procedure, and operative complications (e.g., operative loss of blood), were not associated significantly with an increased risk for the acquisition of infection.[69] Very thin or malnourished patients may be prone to skin break or wound dehiscence, which may increase their vulnerability to infection. In addition, patients with narrowed intervertebral spaces tended to have operations of longer duration, which puts them at risk for the development of infection. A recent study reported an increased infection frequency in children with a percutaneous endoscopic gastrostomy (PEG) tube or urinary or fecal incontinence.[142]

Etiology

The most common bacteria causing intrathecal device–related infection are from the skin flora. Coagulase-negative staphylococci and *S. aureus* lead the list, but *Streptococcus mitis*,[69,349] *Streptococcus* group A or G,[69] *Corynebacterium striatum*,[69] and *Enterococcus faecalis*[151] infections are observed as well. In addition, several studies have reported gram-negative bacteria as the cause of the pump-related infection. Such bacteria include *P. aeruginosa*,[69,151] *Pseudomonas paucimobilis*,[375] *E. coli*,[120] and *Klebsiella pneumoniae*.[374] One case each of *C. albicans*,[120] *Mycobacterium* spp.,[120] and *Acinetobacter baumanii*[498] also has been reported. A rare case of baclofen vial contamination with the fungus *Wangiella* that caused infection was reported as well.[322,375]

Clinical Manifestations

Clinical findings depend on the site of the infection. Patients with more severe infections (i.e., epidural abscess or meningitis) may have symptoms of these infections (e.g., fever, irritability, headache, nerve root pain, or meningeal signs). In some patients, pain experienced during the injection may be the clue, but in many patients, a high level of awareness for possible infection is important because they will have nonspecific signs and symptoms.

Exit-site and superficial catheter-related infections usually cause local inflammation (e.g., swelling, redness), tenderness, and drainage. The more serious deep-tract (tunnel) infections are more difficult to assess. Visible inflammation along the tract or a soft fluctuant fluid collection around it may be the only clue. Fever is not always present.

Diagnosis

Performing a complete physical and neurologic examination may be helpful in some cases. A routine CBC is relatively unhelpful because leukocytosis is not always present. MRI may be useful for diagnosing an epidural abscess and evaluating its extent. The only definitive diagnostic tests are Gram stain and culture of exudate or drainage from the exit site (if available) or an aspirate of the fluid collection along the catheter tract if tunnel infection is suspected or CSF for suspected meningitis. Irrigation of the epidural space with 1 or 2 mL of saline after removal of the pump filter (which should be sent for culture) may help in diagnosing an epidural abscess or empyema.

Treatment and Prophylaxis

If infection has occurred only at the exit site and the superficial catheter tract, local drainage with aggressive cleansing (i.e., topical antibiotics and antiseptics) but without removal of the catheter was suggested.[120] Unfortunately, more severe infections developed (e.g., deep-tunnel and epidural abscess) in some of these patients. In addition, failure of "catheter-sparing" treatment also was reported.[201] Therefore, removal of the catheter should be considered even for mild infections if they do not respond promptly to therapy. In patients with pocket, epidural, and meningeal infections, the intrathecal pump system should be removed as soon as possible and systemic antibiotic therapy initiated (for selection of drugs and doses, see Table 74-4). With the increasing rate of multidrug-resistant staphylococci and the low CSF levels of vancomycin (only 20% to 30% of serum levels), linezolid should be considered as an alternative. Linezolid has good CSF penetration (60% to 70% of the serum level)[552] and has been shown effective in treating severe CNS

*References 40, 69, 100, 120, 344, 415, 554.

infections,[411] including intrathecal infusion pump infection.[232] Although a few studies have reported clinical improvement (and sometimes cure) of tunnel infection or meningitis with the administration of intravenous antibiotics and retention of the catheter, in many cases, the infection recurred when the treatment was stopped.[69,120] A few reports suggest successful treatment of severe pump infections (including meningitis) without removal of the pump system.[59,152,414,506,554] In some of these cases, the pathogen was considered to be of low virulence (e.g., coagulase-negative staphylococci) or colonization, which may be the reason for the success. In most of these cases, however, instillation of antibiotics into the reservoir with cautious flushing of the catheter or repetitive local application of antibiotic-impregnated fleece[374] was combined with systemic antibiotics. In one protocol, "intrapump therapy is started by filling the pump to the total reservoir volume with a 5-mg vancomycin/185-µg baclofen/mL solution and programming the pump to deliver an initial volume of 1 mL/day, and oral baclofen therapy is initiated to prevent withdrawal. Intravenous vancomycin therapy is used concomitantly and serum trough levels are drawn to optimize the dose and avoid toxicity."[506] The main reason for the intrathecal administration of antibiotics is to increase the level of drug in the CSF. Before antibiotics are added to the baclofen infusion, their compatibility with baclofen should be verified or tested (vancomycin is compatible and can be used safely according to Zed and associates).[554]

No guidelines exist on how to treat severe infections of intrathecal pump systems, but in most cases, removal of the pump system while systemic antibiotics are given and then reimplantation appear to be the treatment of choice. In rare cases in which removal of the pump will be detrimental to the patient, a trial of intrathecal administration of antibiotics may be justified, with close observation to ensure that the patient is not getting worse.

Although many physicians use perioperative (or longer) antibiotics for prophylaxis, their efficacy in preventing infection has not been proved. Therefore, prophylactic antibiotics should not be used or, if given, should not be administered for longer than 24 hours after the operation. Because the catheter hub is the most common site for bacteria entry, change of bacterial filters every 2 months is advisable.[20]
